ASTRONOMY.

PART II.

THEORETICAL ASTRONOMY.

Theoretical Astronomy

CHAP. I.

GENERAL PHENOMENA OF THE HEAVENS.

SECT. I.—*Of the Celestial Sphere.*

WHEN a spectator on a clear evening directs his attention to the sky, he perceives a concave hemisphere studded with innumerable brilliant points, all which appear to move in parallel directions, constantly preserving the same distances and relative positions. New groups of stars incessantly follow one another, rising in the east, mounting to a certain height, and then gradually sinking till they disappear in the west. On turning his face towards the north he observes some groups of stars which remain visible during the whole night; wheeling round a certain fixed point, and describing circles of greater or less magnitude, according as they are at a greater or less distance from that point. The same phenomena are observed every successive night; and as the stars present always the same configurations, and succeed each other in the same order, the mind is irresistibly led to the hypothesis of the diurnal revolution of the whole heavens about a fixed axis. This hypothesis implies that the stars move in parallel planes, and that their mutual distances remain invariable. In order, however, to be assured that such is the case, it is necessary to have recourse to more accurate observations, and to refer their successive positions to something that is fixed,—to certain points or planes which do not participate in the general motion.

Horizon. What is most obviously adapted for this purpose is the *Horizon*, or the plane which appears extended all round us, and bounded by a circle of which the eye of the spectator occupies the centre. Let the circle SENW (fig. 1) represent the horizon, C being the centre or place of the observer. Suppose now that a star is observed to rise at a certain point of the horizon A, and, after tracing its circuit in the sky, to set at the point A′; suppose, also, that another star rises at B, and sets at B′; then, if the distances AB, A′B′ are measured by means of some angular instrument, it will be found that AB is equal to A′B′, and that this is the case with regard to any two stars whatever. Since therefore the arcs AB and A′B′ are equal, it follows that the chords A A′, B B′, joining their extremities, are parallel; whence we infer, that if two stars rise successively at the same point of the horizon A, they will also set at the same point A′, a circumstance which is of itself strikingly indicative of the uniformity of the motion of the celestial bodies.

Plate LXXVI. Fig. 1.

Theoretical Astronomy

Through C let a perpendicular be drawn to the chord AA′, meeting the boundary of the horizon in S and N. These two points are the *South* and *North* points of the horizon; and another straight line drawn through C, parallel to A A′, will meet the horizon in E and W, the *East* and *West* points. The four together, namely, S, E, N, W, are called the four *Cardinal* points of the horizon. The horizontal circle is itself denominated the *Azimuth Circle*. Azimuth distances are measured from the North and South points, so that SA is the azimuth distance of a star's rising at A, and SA′ is that of its setting at A′. The complement of the azimuth, or its defect from a right angle, is called the *Amplitude*, which is consequently measured from the East and West points; thus the arc EA is the amplitude of a star's rising at A, or its *ortive* amplitude, and WA′ is that of its setting, or its *occasive* amplitude.

Cardinal points.

Azimuth.

Amplitude.

Conceive a straight line to pass through C, perpendicular to the horizon. This line, which is called the *Vertical*, will meet the visible hemisphere in a point directly above the observer, which is denominated the *Zenith*; the point diametrically opposite, in which the prolongation of the vertical meets the invisible hemisphere, is the *Nadir*. The plane determined by the vertical and the straight line NS is called the *Meridian*, because when the sun reaches it, he is equally distant from the points at which he rises and sets, or, it is mid-day. The great circle formed by the intersection of the meridian with the celestial sphere is the *Meridional* circle; it divides the sphere into the eastern and western hemispheres. Any circle passing through the Zenith and Nadir is called a *Vertical Circle*; that which intersects the meridional circle at right angles, or which passes through the points E and W, is called the *Prime Vertical*.

Zenith.

Nadir.

Meridian.

Vertical.

Let HPZH′ (fig. 2) represent a meridional circle passing through P, that point of the sphere which appears to remain immovable; and let Z be the zenith, and HH′ the horizon. Join PC′, and let it meet the circle in P′. The points P and P′ are denominated the *Poles* of the world, and the straight line PP′ is the *Axis* about which the whole heavens appear to revolve. Let also *uv*, H*g*, *kl*, ÆÆ, *g*′H′, be projections of the paths of different stars

Fig. 2.

Theoretical Astronomy.

on the vertical plane PZH. One of the first circumstances which strikes the attention of the observer is the inequality of the times during which different stars continue visible above the horizon. A star which describes the circle ÆÆ continues visible during a shorter time than one which describes *kl*, and still shorter than one which moves in H*g*. It will be remarked, however, that the interval between two successive risings of the same star is always the same, in whatever point of the horizon it makes its appearance. Those which describe ÆÆ are peculiar in this respect, that the interval between their rising and setting is exactly equal to that between their setting and rising; hence the great circle which they describe is called the *Equator*, and when the sun describes that circle, the days and nights are exactly of the same length. In general, the time during which a star continues visible is greater in proportion as its path is nearer to the visible pole. Those, however, which describe the circle H*g*, or any other parallel, as *uv*, nearer to P, remain always above the horizon; hence such circles are called circles of *Perpetual Apparition*, and the stars describing them are called *Circumpolar Stars*.

Equator.

There are some other technical terms, chiefly employed in the old treatises of astronomy, to denote particular circles of the sphere. A *Secondary* to any great circle, is a circle passing through the poles of its primary: thus the meridian is a secondary to the horizon HH', and to the equator ÆÆ'. The *Colures* are two secondaries to the equator, one of which passes through the equinoctial points, and is called the *Equinoctial Colure;* the other intersects the equator at the distance of 90° from the former, and is denominated the *Solstitial Colure*. The small circles parallel to the equator are simply termed *Parallels;* those which are parallel to the horizon are called *Almucantars;* and the different meridians are likewise termed *Hour Circles*.

Secondaries.

Colures.

Parallels.

Almucantars.

The hypothesis of a spherical revolution implies, as has already been mentioned, that the stars move in parallel planes, or describe parallel circles round the pole. This point, in reference to any particular star, must be determined by observing whether its angular distance from the pole remains invariable during its whole revolution. Let Z (fig. 3) be the zenith, P the pole, and S the place of a star. The arcs PZ, ZS, PS, which join these points on the sphere, will form a spherical triangle, of which the sides PZ and ZS, or the distances of the pole and the star from the zenith, are given by direct observation. The angle PZS is also given in the same manner, for it is equal to the star's azimuth counted from the north point of the horizon. In the triangle ZPS we have therefore given the two sides ZP and ZS, together with the included angle PZS, from which data the polar distance PS is found by the following formula of spherical trigonometry:

Fig. 3.

$$\text{cos. PS} = \text{sin. ZS sin. ZP cos. PSZ} + \text{cos. ZS cos. ZP.}$$

In order to adapt this formula to logarithmic computation, an auxiliary angle φ may be assumed such, that $\text{tan. } \varphi = \text{cos. PZS tan. ZP}$, by the substitution of which the formula becomes

$$\text{cos. PS} = \frac{\text{cos. ZP. cos. (PZS} - \varphi)}{\text{cos. } \varphi};$$

from which the polar distance PS of the star can be easily computed.

On performing the computation for any particular star, PS is always found to be of a constant magnitude, whatever may be the value of PZS, that is, at whatever part of its course the star is observed. Hence we infer that the diurnal motion of the stars round the pole is exactly circular

After having recognised that the celestial bodies move in parallel planes, the next object of the astronomer is to determine whether they revolve with velocities uniform or variable. For this purpose it is necessary to compare, by means of a well-regulated clock, the angular distances between the meridian and the successive positions of a star, with the times elapsed since the star's passage over the meridian. Let *mno* (fig. 4) be the parallel described by a star, and *ss'* two of its successive positions. The arcs *ns*, *ns'*, intercepted between the meridional plane and the planes passing through the axis PP' and the points *s*, *s'*, are measured by the arcs of the equator C*a*, C*b*. Now, it is the result of constant experience, that the number of degrees in the arc C*a* or C*b* is to the number in the whole circumference as the time employed by the star in describing *na* or *nb* is to the time in which it completes a revolution. The time occupied by the star in completing its revolution is called a sidereal day; and the uniformity of the diurnal revolution enables us to calculate the angle CP*s*, which is measured by C*a*, without having recourse to any other observation than that of the star's meridional passage. Denoting a sidereal day by T, the interval of time which elapses while the star describes the arc *ns* by *t*, and the angle at the pole by P, we shall have the analogy $\text{T} : t :: 360 : \text{P}$; therefore $\text{P} = 370° \frac{t}{\text{T}}$; a formula which gives the angle at P, or its measure C*a*. The angles CP*s*, CP*s'*, and *s*P*s'* are called *Hour Angles*, because the arcs which they intercept on the star's parallel of declination correspond to the hours and fractions of an hour into which the sidereal day is divided. For example, if the hour angle *s*P*s'* contain 15°, the two planes passing through *s* and *s'* will intercept on *mn*, the diurnal circle of the star, an arc equal to 15°; consequently there will be 24 such arcs in the whole circumference, each of which will be described in the 24th part of a sidereal day, or in one hour of sidereal time. In consequence of this perfect uniformity of the diurnal motion, the arc which a star describes on its parallel is conveniently measured by the time of its description; and the sidereal day, or the interval between two successive returns of the same star to the plane of the meridian, offers the most perfect *unit of time*, inasmuch as it is exactly the same to all the inhabitants of the earth, and remains absolutely unalterable in all ages, being one of the very few invariable elements of the system of the world.

Theoretical Astronomy.

Fig. 4.

Hour angles.

In fixing the position of a point on a plane surface, geometers usually refer it to two straight lines at right angles to each other, the positions of which are supposed to be known. The same practice is imitated by astronomers, who refer the position of any point on the surface of the sphere to two great circles, which are employed as a system of rectangular co-ordinates, and from which all distances are measured. The equator being a circle of the sphere not subject to any arbitrary condition, but determined by the very nature of the spherical revolution, is obviously well adapted for this purpose. It is therefore universally employed as a term of comparison in assigning the places of the celestial bodies. Suppose an hour circle passing through the star *s* to intersect the equator at *a;* the arc *sa*, which measures on the sphere the distance of *s* from the equator, is called the *Declination* of the star. All other stars situated on the same parallel *mo* have the same declination; and it is invariable for all places of the earth, because it is not affected by the diurnal motion which is performed in the parallel *mo*. The declination is *northern* or *southern*, according as the star is situated in the northern or southern hemisphere. It is expressed in degrees from 0 to 90, proceed-

Method of determining the situations of points on the sphere.

Fig. 4.

Declination.

Theoretical Astronomy.

ing from the equator to the pole. The polar distance Ps is the complement of the declination, because $Ps + sa = 90°$. In order to distinguish s from all other stars which may be situated on the same parallel, we must also know the point a of the equator to which it corresponds; and for this purpose it is necessary to select a point γ of the equator for the origin of the co-ordinates. This point ought to be independent of the diurnal motion, otherwise its position could only be determined for a single instant of time; and it must be such that it can be readily found, in whatever part of the earth the observer may be situated. Astronomers have agreed to employ for this purpose the point determined by the intersection of the equator with another very remarkable circle of the sphere, of which we shall speak hereafter, and to count the degrees on the equator, setting out from γ, from 0 to 360, in the direction opposite to that of the diurnal motion, or from west to east. The arc γa, which measures the distance between γ and a, is called the *Right Ascension* of the star s: it is also the right ascension of any other star situated in the hour circle PsP'. It is measured by the interval of time which elapses between the transit of the star s over the meridian, and that of the point γ, which has been chosen as the point of departure. It may be remarked that the point γ is also the origin of sidereal time; that is to say, the time is counted 0 hour 0 min. 0 sec. when that point passes the meridian.

Right Ascension.

From these definitions it is easy to conceive the general method of forming a catalogue of stars. A clock being regulated to sidereal time, and marking 0 hour at the instant of the transit of the point γ (or any star chosen arbitrarily), the hours, minutes, and seconds, are noted at which the stars successively pass the axis of the transit instrument, together with their respective altitudes at the same instant. These observations give the right ascensions and declinations; for the time is easily converted into degrees, at the rate of 15° an hour, or by the formula given above for determining the hour angle. If the star s pass the meridian one hour after s', the arc $a\,b$, which measures the distance between their horary circles, PaP', PbP', is 1 hour or 15°; and the declination of a star s which moves in the parallel kl (fig. 2) is $Æl = H'l - H'Æ$, that is, equal to the difference between its meridional altitude and the complement of the altitude of the pole H P. Modern celestial charts are constructed on the principle of assigning to each star the place indicated by the values of these two co-ordinates; and as observation proves that the mutual distances and relative positions of the stars scarcely undergo any sensible variation, a globe or chart once constructed will serve to represent the state of the heavens for at least a long series of ages.

Fig. 2.

Explanation of the phenomena.

Having now considered the general phenomena of the diurnal revolution, and explained the terms that are technically employed in assigning the positions of the celestial bodies, we may next proceed to inquire how these phenomena are to be accounted for,—whether the stars are really in motion, as they seem to be, or if the apparent motion is only an illusion occasioned by the revolution of our own earth. The perfect uniformity of the motions of the different stars renders it exceedingly improbable that they are disconnected; hence the simplest view of the phenomena is obtained by substituting for each star its projection on the celestial sphere, at an infinite distance, and supposing this sphere, with the projections of all the stars, to revolve in 24 hours from east to west round an immovable axis. But it is easy to see that the phenomena will be equally well explained by supposing that the starry firmament is absolutely at rest, and that the earth revolves in the same time, round the same axis, but in an opposite direction, from west to east. In both cases the stars remain immovable, the phenomena are exactly the same, and, relatively to *Spherical Astronomy*, in which we only concern ourselves with the *apparent* motions, it is absolutely indifferent which of the two hypotheses we adopt. They are both only modes of explaining certain appearances; and the one may be employed which renders the explanation most simple and perspicuous. The proofs of the earth's motion will go on accumulating as we proceed. At present we need only remark, that as the organ of sight makes us acquainted with the existence of relative, and not of absolute motion, it is impossible to decide, merely from appearances, whether the motion we perceive is real or otherwise; for whatever motion one body may have in respect of another, it is always possible to explain the phenomena by supposing it to be perfectly at rest, and the other to move in an opposite direction. The conclusions which we draw from the *optical* effects of motion afford no mathematical certainty with regard to the cause of that motion. The hypothesis of the revolution of the sphere is attended with innumerable and insurmountable difficulties. The distance of the nearest fixed star from the earth is not less than 350,000 times the distance of the sun; a distance which light, prodigious as its velocity is, would not traverse in less than five years. This immense line, therefore, supposing the heavens to revolve round the earth, would form the radius of a circle, the circumference of which, six times larger, would be passed over by the star in the space of 24 hours; its velocity must therefore be $6 \times 5 \times 365 = 10950$ times greater than that of light. This velocity, which is nearly equivalent to 2100 millions of miles in a second of time, is so enormous that it baffles the utmost efforts of the imagination to form any conception of it; and the supposition of its existence will appear still more revolting when we reflect that the distance of the nearest star is probably many thousand times less than that of the Milky Way. If we ascribe the motion to the earth, its velocity, though it may still be supposed great, is moderate in comparison of many well-known phenomena of nature. A point on the equator will describe in 24 hours a circle of about 25,000 miles, or about 17 miles in a minute; a velocity somewhat exceeding that of sound, but 7400 millions of times less rapid than the preceding.

Theoretical Astronomy.

In all that has hitherto been said respecting the apparent motion of the starry sphere, we have only had regard to the innumerable multitude of stars which constantly maintain the same relative situations, and which are in consequence called *Fixed Stars*. There are, however, several other bodies, some of them remarkable on account of their splendour, which, besides participating in the general motion, have peculiar motions of their own, and are incessantly shifting their positions among the fixed stars. An attentive observation of the state of the sky during a few successive evenings, will suffice to show that there are some stars which have in the mean time changed their places; and, on continuing to observe them, they will be found to separate themselves from particular constellations, and gradually but imperceptibly to approach others, till they at length appear, after unequal intervals of time, in an opposite quarter of the heavens. From this circumstance they were designated by the Greeks *Planets*, that is, *wandering stars*, in contradistinction to those which obey only the law of the diurnal motion. Besides the sun and moon, there are five discernible by the naked eye, and which have consequently been known from the remotest ages. These are Mercury, Venus, Mars, Jupiter, and Saturn. Twenty-eight others, including Neptune, Uranus,

Theoretical Astronomy

and the small planets, have been discovered by the aid of the telescope. Astronomers, with a view to abbreviate their descriptions, have appropriated a certain symbol to each of these planets, as well as to the sun and moon: thus, for the older planets, in the order of distance from the sun, the names and characteristics are as follows:—

The Sun	☉	Ceres	⚳
Mercury	☿	Pallas	⚴
Venus	♀	Jupiter	♃
Mars	♂	Saturn	♄
Vesta	⚶	Uranus	♅
Juno	⚵		

The Earth, which, as we shall afterwards see, is also a planet, and takes its place between Venus and Mars, has for its symbol ⊕, and the moon ☽. Venus, Jupiter, and sometimes Mars, are distinguished by their extraordinary brilliancy. Mercury, on account of his proximity to the sun, is rarely visible to the naked eye. Uranus, discovered by Sir W. Herschel in 1778, can with difficulty, by reason of his great distance, be perceived without a telescope. Ceres, and the other planets discovered since 1801, are extremely small in size, and can only be seen with the aid of the telescope.

Motions of the sun and moon.

Of all the celestial bodies, the most interesting to us are the sun and moon; and their peculiar motions have accordingly, in every age of astronomy, been studied with the greatest attention. The proper motion of the moon is particularly remarkable. In the course of a single night she separates herself very sensibly from the stars in her vicinity, moving over a space nearly equal to her own breadth in an hour, and completing a whole circuit in about 27 days. The sun moves with much less velocity, but his motion is still sufficiently apparent. If we take notice of the stars which immediately follow him when he sinks under the horizon, we shall find that in the course of a few nights they will be no longer visible. Others which, some time previously, did not set till long after him, have taken their places and now accompany the sun. In the morning similar appearances present themselves, but in a contrary order. The stars which appear in the eastern horizon at sun-rise, are, after a few days, considerably elevated above it at the same time. Thus the sun seems to fall daily behind the stars, by insensible degrees, till at last he appears in the east when they are about to set in the west. To account for these appearances, the ancients supposed the sun's diurnal motion to be really slower than that of the stars; hence they supposed him to be attached to a different sphere. For like reasons they ascribed particular spheres to the moon and each of the planets; and as no trace of these imaginary spheres is perceptible in the heavens, they next supposed them to be crystalline and transparent. The appearances are explained equally well, and with infinitely greater simplicity, by ascribing to the sun a proper motion, in a direction opposite to that of the diurnal rotation of the sphere, in consequence of which he advances to meet the stars, instead of falling behind them.

The greater part of the observations of the early astronomers had for their object the determination of the positions of the stars relatively to the sun at his rising and setting, by which they fixed the seasons, and regulated the operations of agriculture. They distinguished all these phenomena by technical terms, which occur very frequently in the works of the ancient poets, particularly in Hesiod and in Ovid's *Fasti*. A star which rises at the same time with the sun is effaced by his light, and is said to rise *cosmically* (*ortus cosmicus*). Soon after, when the sun by his proper motion has advanced so far to the east that the star can be perceived on the eastern horizon in the morning twilight, it disengages itself from the sun's rays, and is said to rise *heliacally* (*ortus heliacus*). At the end of six months, the sun being diametrically opposite to the same star, it sets as the sun rises, and in this case it is said to set *cosmically* (*occasus cosmicus*): at nearly the same time it rises when the sun sets, and is said to rise *acronically* (*ortus acronyctus*). The sun afterwards begins to approach the star, till he advances so near that it is again about to be effaced by his light; it is now said to set *heliacally*, or just so long after the sun as to be visible when he has disappeared (*occasus heliacus*). At the end of a year, the star again rises and sets at the same moment with the sun; it is now said to set *acronically* (*occasus acronyctus*). These distinctions, and the ancients had several others of the same kind, which are all defined by Ptolemy, are now scarcely ever mentioned. They have lost the whole of their interest since, in the progress of astronomy, more certain methods have been discovered of determining the commencement of the year and the seasons.

Theoretical Astronomy.

Stations and retrogradations.

The proper motions of the planets are in general, like that of the sun, in a direction opposite to the diurnal motion, or from west to east, among the stars: but they do not preserve the same character of uniformity; the planet sometimes becomes stationary among the fixed stars, and even advances from east to west in the direction of the diurnal motion. In this case it is said to *retrograde*. This retrograde motion is, however, not of long continuance. After having been accelerated during a short time, it begins to relax. The planet again becomes *stationary*, and then resumes its *direct* motion from west to east. These phenomena were observed in the remotest antiquity, and their explanation formed the principal part of the rational astronomy of the Greeks and the Arabians.

Comets.

Besides the planets, other bodies occasionally make their appearance in the heavens, which, by reason of the extraordinary phenomena they exhibit, have been frequently contemplated with terror and dismay, and regarded by superstitious ignorance as harbingers of calamity, and precursors of the divine vengeance. These bodies shoot down, from the remote regions of space, with inconceivable velocity, towards the sun. At their first appearance they are small; their light is feeble and dusky; and they are generally accompanied by a sort of nebulosity or luminous tail, from which they have derived their appellation of *Comets* (*coma*, hair). As they approach the sun, their apparent magnitudes and brilliancy greatly increase, and the nebulosity sometimes occupies a large portion of the heavens, presenting a magnificent and astonishing spectacle. Having attained the point of their orbits nearest the sun, they again recede to enormous distances, and vanish by insensible degrees. They differ from the planets not only by the appearances they present, but also by the diversity of their motions; for, instead of being confined to a particular zone, and moving from west to east, they traverse the sky indifferently in all directions. They are visible only in a small part of their orbit, which, being near the sun, is passed over with prodigious rapidity. They seldom continue visible longer than six months. Their number is entirely unknown, but during the last two centuries upwards of 170 have been observed, and their orbits computed.

Thus we recognise three distinct classes of celestial bodies; the planets, the comets, and the fixed stars. It is the business of the astronomer to determine the positions of these bodies in the heavens; to observe their motions, and measure them with precision; to discover the laws by which their courses are regulated; and from these laws to assign the past or future state of the heavens

Theoretical Astronomy.

at any given instant of time. The fixed stars form infinitely the most numerous class; but their motions being sensibly uniform, and their mutual distances invariable, the principal object with regard to them is to determine their places and relative positions. The comets in general return only after long periods; and observations are not yet sufficiently numerous to allow any certain deductions to be made with respect to their nature and constitution. The planets present a great variety of curious phenomena; they are always within our view; observations on them may be multiplied indefinitely; and for this reason, as well as on account of their proximity, and their forming a system of which the earth constitutes a part, they present by far the most interesting objects of astronomical study.

Sect. II.—*Of the Globular Form of the Earth, Parallax, and Refraction.*

Having now considered the general phenomena of the diurnal motion, we proceed next to inquire into the form of the earth, and our situation with respect to the centre round which the celestial sphere appears to revolve. The plane of the horizon seems to be stretched out indefinitely till it actually meets the sky; but this illusion is quickly dissipated by transferring ourselves from one place to another on the surface of the earth, and attending to the phenomena which such a change of place gives rise to. Let an observer, for example, set out from any given point in the northern hemisphere, and proceed directly south. In proportion as he advances, the stars in the southern region of the heavens will be elevated more above the horizon, and describe larger segments of their diurnal circles, while new ones come into view which were invisible at the station he left. On the other hand, the polar star, with those in its vicinity, will be depressed, and some stars which before continued above the horizon during the whole time of their revolution will now rise and set. The planes of the diurnal circles become also more perpendicular to the horizon, so that the aspect of the heavens is entirely changed. If, instead of advancing in the direction of the meridian, the spectator proceeded towards the east or west, he would in this case also remark that his horizon constantly shifted its position. A star will pass his meridian sooner as he advances eastward, or later as he travels westward; in short, by a change of place in any direction whatever, the perpendicular to the horizon, or the plumb-line, will correspond to a different point of the heavens. The plane of the horizon is therefore variable, and its variation by insensible degrees indicates with the greatest evidence the rotundity of the earth. Experience also shows that a spectator sees more of the terrestrial surface in proportion as he is elevated above it; and that on a mountain surrounded by the sea, or standing in the middle of a level plain, the horizon appears equally depressed all round, which is the distinctive feature of a spherical curvature. In fig. 5 let O be the place of a spectator on the summit of a mountain, the straight line H H will represent his horizon, and O*h*, O*h'* the directions of visual rays to the remotest visible points on the surface of the earth. The inclinations of these lines to the plane of the horizon, or the angles HO*h*, H'O*h'* are called the *apparent depression*; and these being always observed to be equal to each other, it follows that the curve *h*A*h'* is a circle. On the Peak of Teneriffe, Humboldt observed the surface of the sea to be depressed on all sides in an angle of nearly 2°. The sun arose to him 12 minutes sooner than to an inhabitant of the plain; and from the plain, the top of the mountain appeared enlightened 12 minutes before the rising or after the setting of the sun. The same phenomena, though on a smaller scale, are observed with regard to every mountain or elevation on the earth. Another familiar illustration of the globular figure of the earth is derived from the successive and gradual disappearance of a ship which leaves the shore and stands out to sea. The hulk disappears before the sails and the rigging, and the top of the mast is the last part that is visible. The ship thus appears gradually to sink under the horizon, exactly in the same manner as she must necessarily do on the supposition that the surface of the sea is spherical. The appearance of the moon at the time she is eclipsed is also demonstrative of the roundness of the earth. When the moon penetrates the shadow of the earth, the line which separates the illuminated from the eclipsed portion of the disk is circular; evidently proving the conical form of the shadow, and consequently the roundness of the body by which the shadow is projected. From all these considerations, it is inferred with the highest certainty that the earth with its waters forms a round mass, isolated in space.

Theoretical Astronomy.

The globular form of the earth is a property common to it with the other bodies which compose the planetary system. The sun and moon are evidently round bodies; and when the planets are examined through a telescope their disks appear sensibly circular; and as they are known to have a motion of rotation, in consequence of which they successively present different points of their surfaces to the earth, the uniform roundness of their disks may be taken as a conclusive proof of their sphericity. We shall by and by have occasion to remark other striking analogies between the planets and the earth.

Sensible and rational horizon.

Since the figure of the earth is spherical, the horizontal plane cannot coincide with any considerable portion of its surface. It may be defined to be the plane which touches the earth at any given point, and is perpendicular to the vertical line, or the direction of gravity at that point. The *Sensible Horizon* of any place is the plane which passes through the eye of the spectator, perpendicular to the plumb-line at that place. The *Rational Horizon* is a plane parallel to this, passing through the centre of the earth. The particular phenomena of different places depend on the position of their horizon with respect to the planes of the apparent diurnal motion of the sun and stars. The rational horizon of a place on the equator passes through the poles, and divides equally the equator and its parallels. Hence the days and nights are always equal in such places, and each of the stars performs one half of its revolution above, and the other below its horizon. The circles of diurnal motion are all perpendicular to the horizon, and therefore the inhabitants are said to be under a *Right Sphere*. If a spectator could place himself directly under the pole, his horizon would coincide with the equator, and the whole of the northern celestial hemisphere would be within his view, while no part of the southern hemisphere would be visible to him, on account of its being always beneath the horizon. The circles of the diurnal motion being parallel to the equator, and consequently also to the horizon, the fixed stars would never either rise or set. A spectator thus situated is said to be under a *Parallel Sphere*. In intermediate places the circles of the diurnal motion are oblique to the horizon, one pole being always elevated above it, and the other equally depressed below it. The stars whose distances from the elevated pole are not greater than the arc of its elevation above the horizon never set, while those within the same distance of the depressed pole never rise. These phenomena belong to all places situated between the equator and the poles, and the inhabitants of such places are said to be under an *Oblique Sphere*.

Theoretical Astronomy.

The situation of a place on the surface of the earth is determined by two co-ordinate circles, in the same manner as that of a star on the celestial sphere. Let Z (fig. 2) be a place of which the position is required to be assigned with reference to circles of the terrestrial sphere, analogous to those which we have described as belonging to the sphere of the heavens. Since the axis of the celestial sphere passes through the centre of the earth, we may suppose the poles of the world, the equatorial circle, and the meridians, to be transferred to the earth's surface, so that the same figure may represent either the celestial or terrestrial sphere. The intersection of the plane P Z Æ with the surface of the earth is the terrestrial meridian of the place Z, and the straight lines C Z, C Æ, in that plane, intercept an arc of the terrestrial meridian between Z and the equator, containing as many degrees as the arc of the celestial sphere which measures the declination of the zenith of the place Z. The angle Æ C Z which is measured by the meridional arc Æ Z is called the *Geographical Latitude* of Z. But in order to particularize the point at which the equator is intersected by the meridian, it is necessary to assume some point of the equator to which all the other points of that circle may be referred. The meridian passing through the assumed point is called the *First Meridian;* and the angular distance between the planes of the first and any other meridian measured by the equatorial arc intercepted by these planes on the equator, is called the *Geographical Longitude* of the place through which the last meridian passes. The longitude is said to be *east* or *west*, according as the degrees of the equator are counted from the first meridian towards the east or west. It is usual to reckon the degrees towards the east, all round the globe, or from 0 to 360°. From these definitions it is evident that the geographical latitudes and longitudes are exactly analogous to the declinations and right ascensions on the celestial sphere. The first point of the terrestrial equator cannot be determined by any star or fixed point in the heavens, on account of the diurnal motion; it is therefore necessary to fix its position by means of known places on the earth; and geographers are in the habit of assuming as the first meridian that which passes through the capital city or principal observatory of their country. The choice is of no importance; for in geography, as in astronomy, what is essential to be known is only the *difference* of longitudes or meridians, in order to reduce the situation of a place, or observations which have been made at it, to any indicated meridian.

Fig. 2.

Magnitude of the earth.

The length of the terrestrial radius is a very important element in astronomy, inasmuch as it furnishes the observer with the only scale by which he can estimate the distances of the sun, moon, and planets. On the supposition that the figure of the earth is perfectly spherical, the general principles on which its magnitude may be determined are sufficiently obvious; but the accurate determination of its actual dimensions is attended with great practical difficulties, which can only be overcome by the perfect instruments and refined science of modern times. Eratosthenes seems to have been the first who made use of astronomical methods to determine the circumference of the earth, or the length of the meridian. He remarked that, at Syene, in the Thebais, the sun on the meridian, at the time of the summer solstice, was vertical; and that at Alexandria, at the same time, his zenith distance was 7° 12′. Now let S (fig. 6) be the sun, vertical to M, and Z the zenith of Alexandria, C being the centre of the earth, and O Alexandria. The angle Z O S is the sun's zenith distance, which was observed to be 7° 12′. But $ZOS = ZCS + OSC$; whence, as the angle O S C, which is extremely small on account of the sun's great distance, may be neglected in the calculation, the angle Z C S at the centre is also equal to 7° 12′, and therefore the whole circumference equals $\frac{360°}{7° 12'} \times M O$. To obtain the length of the meridian, it is therefore only necessary to measure the arc M O. Eratosthenes assumed the distance between Syene and Alexandria to be 5000 stadia; hence the circumference of the earth $= \frac{360°}{7° 12'} \times 5000$ stadia $= 250{,}000$ stadia. The uncertainty which exists respecting the length of the Egyptian stade prevents us from deriving any precise information from this rude attempt to estimate the dimensions of the globe.

Fig. 6.

Theoretical Astronomy.

The method which has just been described takes for granted that the meridian is exactly circular,—an assumption which, even supposing the method perfect in all other respects, would lead to erroneous results, especially in an arc of so great a magnitude as seven degrees. In a small arc, of 1° for example, the error arising from the non-sphericity of the earth will be insensible; for it is certain, from the phenomena before explained, that the deviation from the spherical figure is not very considerable; and besides, whatever the nature of the meridional curve may be, it will sensibly coincide with its osculating circle, throughout the extent of an arc of 1°. It has been found by numerous and accurate experiments, that the lengths of arcs of 1° on the same meridian are longer in proportion as we advance nearer the pole. Hence, on account of the similarity of the isosceles triangles of which these arcs form the bases, their sides, or the terrestrial radii, must also be longer, and consequently the convexity of the earth is less towards the pole than at the equator. The surface of the earth is extremely irregular, even independently of the inequalities occasioned by mountains and cavities; yet it has been discovered that the meridional curves differ almost insensibly from ellipses; whence it is concluded that the figure of the earth is an ellipsoid of revolution about its shortest axis. In comparing the results of the various measurements which have been made with the formulæ belonging to the dimensions of such a body, this conclusion has been fully verified; and the lengths of the arcs, the ellipticity, the distance of the pole from the equator, and, in short, all the elements of the spheroid, have been determined. The results of theory and observation give an ellipticity amounting very nearly to $\frac{1}{305}$; that is to say, the equatorial is to the polar diameter in the ratio of 306 to 305. The following may be regarded as a very near approximation to the dimensions of the earth in English miles:—

Semidiameter of the equator	3963·7
Semidiameter of the pole	3949·8
Semidiameter at the latitude of 45°	3956·2
Ellipticity $\frac{1}{305}$	13
Length of 1° of the meridian	69·06
Quarter of the meridian of Paris	6214·47

The figure of the earth is one of the most difficult and most important questions of astronomy; and as our limits will not permit us to treat it in this place with all the details which its importance renders necessary, we shall reserve, for a separate article, an account of the different geodetical operations which have been undertaken with a view to determine it, together with the development of the mathematical theory of its equilibrium. See FIGURE OF THE EARTH.

In describing the phenomena of the diurnal revolution, we have supposed the eye of the spectator to be placed

Theoretical Astronomy.

in the centre of motion, on which supposition the apparent and true places of the celestial bodies will be the same. This, however, as is evident, can only be rigorously true in respect of one point of the earth's surface, and is therefore most probably not true of any. Astronomers have on this account agreed to refer all the motions to the centre of the earth; that is, to consider the centre of the earth as the centre of the celestial sphere, and to regard as the true geocentric place of a star, that at which it would appear to a spectator placed at the centre. But the spectator is necessarily placed at the surface. In order, therefore, to render observations made at different stations on the earth's surface comparable with one another, we must consider what changes will be produced in the apparent positions of the celestial bodies, in consequence of their being observed from a point not situated in the centre of motion.

Fig. 6. Parallax.

Let O′ and O (fig. 6) be two stations on the earth's surface on the same meridian, from both of which a star S is observed at the same time. As an object is always seen in the direction of the visual ray, the spectator at O will refer the star S to a certain point I on the surface of the celestial sphere, while the spectator at O′ will refer it to a different point I′ in the direction O′ I′; and the difference of the apparent places I and I′ depends on the magnitude of the angle OSO′, which is subtended by the chord of the arc OO′. If a third spectator could be placed at C, the centre of the earth, the same star would appear to him in the direction CS, and be referred to its true place on the sphere at Q. Now, the difference between the angles ZOS and ZCS, that is, the angle OSC, under which the radius of the earth is seen by an observer at S, is called the *parallax* of S. On account of the great distance of the fixed stars, this angle is insensible with regard to the least distant of them; it is, however, very sensible in the case of the moon, with regard to which it amounts to about 1°. The greatest parallax of the nearest planets does not exceed 30″.

From the definition which has just been given, it appears that the parallax of an object is the angle comprised between two lines drawn from the object, the one to the centre of the earth, and the other to any point whatever on its surface. But it is evident, that while the distance of S from the earth remains constant, the angle OSC will vary with the angle ZOS, that is, with the distance of the star from the zenith, or its altitude above the horizon.

Fig. 7.

Let OH (fig. 7) represent the horizon. It is easy to see that the angle OSC will have its greatest value when OS touches the surface of the earth, or coincides with the horizon OH, that is, when the angle ZOS = 90°. It is equally evident that the parallax OSC vanishes entirely when the line CS coincides with CZ, that is, when the object is in the zenith of the observer at O; hence the parallax depends on the altitude of the object, according to a law which we now proceed to determine.

Fig. 7.

In the triangle OSC (fig. 7), we have sin. OSC : sin. SOZ : : CO : CS, whence sin. $OSC = \frac{CO}{CS}$ sin. SOZ. Let the angle SOZ, or the zenith distance of the object = Z, the semidiameter of the earth OC = a, the distance of the object CS = r, and the parallax OSC = p, we have then sin. $p = \frac{a}{r}$ sin. Z. On account of the smallness of the angle p, which, as we have mentioned, in no case exceeds 1°, the arc may be substituted for the sine (for their difference even in an arc of 1° does not exceed 0″·18): the above expression therefore becomes $p = \frac{a}{r}$ sin Z; that is to say, the parallax of an object is proportional to the sine of its zenith distance. At the zenith, Z = 0, therefore sin. Z = 90, and the parallax vanishes: at the horizon, Z = 90°, and sin. Z = 1; the parallax, therefore, becomes equal to $\frac{a}{r}$. In this case it is at its maximum, and is denominated the *Horizontal Parallax;* in all other cases it is called the *Parallax of Altitude.* Denoting the horizontal parallax by P, we have $P = \frac{a}{r}$, whence

$$p = P \sin. Z;$$

that is to say, *the parallax of altitude is equal to the horizontal parallax, multiplied by the sine of the apparent zenith distance.* It is evident that the apparent altitude SOH is always less than the true altitude SBH, by the whole amount of the parallax; the effect of the parallax is therefore to depress the object, or increase its zenith distance; hence, if θ be the apparent altitude of the star, and θ' its true altitude, θ' will be found from the equation $\theta' = (\theta + P)$ sin. Z.

From the above results it is manifest, that if the horizontal parallax can be by any means determined, the parallax at any other altitude will be found at the same time. The determination of the horizontal parallax is, however, attended with considerable difficulty, and various methods have been proposed and practised to ascertain its exact amount, modified by particular circumstances in the cases of the different celestial bodies. The method, however, which serves as the basis of all the others is extremely simple, and exactly analogous to that by which the distance of a remote object is determined on the surface of the earth. Suppose two observers to be stationed at the points O and O′ (fig. 6), of which the latitudes are known, and which are both situated on the same meridian, and let them simultaneously observe the zenith distances of the star S; these observations will give the angles ZOS, Z′O′S, whence their supplements SOC and SO′C become known at the same time. A third angle of the quadrilateral figure SOCO′, namely OCO′, is also known, being measured by the meridional arc OMO′, the difference or sum of the latitudes of the two observers, according as they are on the same or opposite sides of the equator. The two sides also, CO and CO′, being semidiameters of the earth, are supposed to be known; every part of the quadrilateral figure is therefore determined, and its diagonal CS may be calculated by the rules of plane trigonometry. But when CS is determined, the horizontal parallax is obtained immediately from the formula $P = \frac{a}{r}$, that is, $P = \frac{CO}{CS}$. On this principle the horizontal parallax of the moon was determined by Lacaille and Lalande, the former observing at the Cape of Good Hope, and the latter at Berlin; and the parallax of Mars by Lacaille at the Cape, and Wargentin at Stockholm.

Fig. 6.

Let us suppose two lines to be drawn from the centre of a planet touching the surface of the earth in points diametrically opposite; the inclination of these two straight lines is the double of the horizontal parallax; but the same angle also measures the diameter of the earth as seen from the planet: hence the horizontal parallax of a planet is equal to the apparent semidiameter of the earth at the distance of the planet. From this consideration the true diameter, and consequently the volume, of a planet may be found by measuring its apparent diameter, that is, the optical angle under which its diameter appears when seen from the earth Let d be the apparent, and D the true diameter of a planet; the angle $\frac{1}{2}d$ is comprised between two straight lines drawn from the

Theoretical Astronomy

earth, the first of which is directed to the centre of the planet, and the last is a tangent to it: hence $\frac{1}{2}$ D = r tan. $\frac{1}{2}d$ or r sin. $\frac{1}{2}d$, according as r is the line which touches the planet or that which is directed to its centre. Now, on account of the smallness of the angle $\frac{1}{2}d$, the sine and tangent are sensibly equal to the arc; we may therefore suppose in all cases D = $r\,d$. Combining this with the equation $P = \frac{a}{r}$, we deduce $\frac{D}{a} = \frac{d}{P}$; which gives the ratio between the true diameters of the planet and the earth in terms of the apparent magnitude and horizontal parallax of the planet. It follows also from this last equation that $\frac{d}{P}$, or the ratio of the apparent diameter and parallax of a planet, is constant; the horizontal parallax may therefore be found at any time whatever by measuring the planet's diameter.

From the equation $P = \frac{a}{r}$, we have $r = \frac{a}{P}$; that is, the distance of a planet from the earth is known in terms of its parallax and the earth's semidiameter. The parallaxes, therefore, give the ratio of the distances of all the planets from the earth, and consequently of their distances from one another, and from the sun; hence the radius of the earth furnishes the scale by which the astronomer measures the dimensions of the whole solar system, and the magnitudes or volumes of all the bodies of which it is composed. On this account the accurate determination of the parallaxes of the celestial bodies is a problem of great importance in practical astronomy.

Fig. 7.

It is evident from the mere inspection of the figure, that the plane in which the straight lines C S and O S are situated is the vertical plane passing through S, consequently the whole effect of the parallax is to diminish the altitude of a planet in its vertical circle. When the observation, therefore, is made in the meridian, the effect of the parallax is to alter the declination, without producing any change whatever in the right ascension of the planet. Out of the meridian it is necessary to have regard to the azimuth or hour angle, as well as to the altitude, in calculating the correction due to the parallax. When we suppose the earth to be spherical, the formulæ for the calculation of the parallax are extremely simple, because the radius is constant, and the vertical line, or perpendicular to the surface of the earth, passes through its centre. But in the case of the true or elliptical figure of the earth neither of these circumstances takes place. The radius in this case is variable, and must be determined by a particular process of computation for every point on the meridian; and the vertical line, with reference to which the latitude of the place and the altitudes are determined, does not pass through the centre of the earth, but makes different angles with the axis. These circumstances render the calculation of the parallax a matter of much greater complication and difficulty.

The term parallax in its general signification properly denotes *change* of place. There are consequently various kinds of parallaxes, such as parallax of right ascension, of declination, longitude, latitude, &c. In what has preceded, we have supposed the earth to be at rest in the centre of the universe, and therefore have had regard solely to the variations produced in the apparent diurnal motions by the eccentric position of the observer on the surface of the earth, and which are comprehended generally under the denomination of the *diurnal* parallax.

The effects of the diurnal parallax are only sensible with regard to those bodies of which the distance from the earth is not so great as to be incomparable with the earth's semidiameter. That the apparent place of an object must be changed in consequence of a change in the situation of the observer, is a simple geometrical truth which no experiment was required to discover. The first observers must accordingly have anticipated a parallax in all the celestial bodies; and it was doubtless only after considerable experience that they admitted the existence of any exception to the general law. There is, however, another cause of variation in the apparent positions of the celestial bodies also connected with the earth, the existence of which could not be known *a priori*, but must have been discovered by experience alone. We allude to the refraction of the rays of light in passing through the earth's atmosphere.

Theoretical Astronomy.

Refraction.

The angular distance between two stars is found to undergo very sensible variations at different hours of the day. This phenomenon cannot be explained by any proper motion of the stars, because it evidently depends on their altitude above the horizon; and the differences are found to be the same daily at the same altitude. It is most striking when we compare a star which, without setting, passes the meridian twice a day, once near the zenith, and the second time near the horizon, with another star situated very near the pole, and of which the altitude is consequently nearly invariable. It will be found that at the time of the first transit the distance between the two stars is greater than at the second by nearly half a degree. It is evident, therefore, that the phenomenon consists in diminishing the distance between a star situated in the horizon and the visible pole, that is to say, in elevating the stars, whereas the effect of the parallax is to depress them. The refraction also takes place in an equal degree with regard to the fixed stars, and even the moon and planets, without being in any degree modified by the great differences in the distances of the celestial bodies, contrary in this respect likewise to the parallax, which depends entirely on the distance. The reason of this will be evident from the consideration of the physical cause of the phenomenon.

Theory of refraction.

According to the known principles of optics, a ray of light, in passing obliquely from one transparent medium into another of a different density, does not hold on in its rectilinear course, but is refracted, or bent towards the denser medium. Now, the atmosphere which surrounds the earth may be regarded as composed of an infinity of concentric spherical strata, the densities of which are greater in proportion as they are nearer to the earth's surface. When a ray of light, therefore, proceeding from a star enters the atmosphere, it is inflected towards the earth, or bent so as to form a smaller angle with a perpendicular to the surface of the earth; and this inflection will be increased by every successive stratum of the atmosphere through which the light passes. In fig. 8, let Fig. 8. AA′, BB′, CC′, represent the boundaries of the successive strata, which, for the sake of illustration, we here suppose to have a finite thickness. A ray of light proceeding from S comes in contact with the highest stratum of the atmosphere AA′ at a. The molecular attraction of this atmospherical stratum, acting in the direction of a normal to AA′ at a, causes the luminous ray to deviate from the direction S x, and assume another, $a\,y$, in which it would continue to move if the atmosphere were equally dense from AA′ to the earth. But in the course of its progress the ray penetrates another denser stratum at b, and consequently suffers another inflection; so that instead of proceeding in the direction $a\,y$, it is bent into a new direction $b\,z$, more nearly perpendicular to the concentric strata. A similar effect is produced at c, so that the luminous ray, when it finally reaches the observer at O, has as-

Theoretical Astronomy.

sumed the direction *c* O. In its progress from *a* to O, it has therefore successively moved in the direction of the sides of the polygon *a*, *b*, *c*, O; and to the spectator at O, the star from which it proceeded, instead of appearing in its true place at S, will appear to be at S′, or in the last direction of the visual ray. Now, if A A′ is the most elevated stratum of the atmosphere into which the ray enters in the direction S *a*, it is clear that the whole effect is produced by the atmospherical strata situated below A A′, and that the length of S *a* is perfectly indifferent; hence the refraction is entirely independent of the distance of the stars, provided they are beyond the limits of the earth's atmosphere.

The decrease of the density of the atmosphere, from the surface of the earth upwards, follows the law of continuity, or takes place by insensible degrees; so that the luminous ray, in traversing the atmosphere, enters at every instant into a denser medium, and is therefore continually brought nearer and nearer to the vertical direction. Hence the true path of the ray is curvilinear, and concave towards the earth, as represented in fig. 9. This is equivalent to the supposition that the thickness of the different concentric strata of uniform density is infinitely small, and that the light, as it successively penetrates each, deviates from its former path by an infinitely small angle, which may be considered as the differential of the refraction, the total amount of which will therefore be obtained by integration. The direction of the ray, when it reaches the eye of the observer, is the tangent to the last portion of its curvilinear path; and the apparent zenith distance of the star will be ZOS′, while the real zenith distance is ZOS. The difference of these two angles, namely S′OS, is what is denominated the *Astronomical Refraction*. It is evident that the whole path of the ray is confined to the vertical plane, in which the star and the eye of the observer are situated; for the earth and its atmosphere being very nearly spherical, that plane will divide the strata symmetrically; there will therefore be no displacement in a lateral direction, or no refraction out of the vertical plane. When the observed star is due north or south, the vertical plane is the plane of the meridian; hence, in meridional observations, the whole of the refraction, like that of the parallax, takes place in declination, while the right ascension remains unaltered.

Fig. 9.

Law of refraction.

It is evident that the amount of the refraction is greater in proportion as the observed star is nearer to the horizon; for in this case the luminous rays strike the tangent planes of the atmospherical strata more obliquely, and have besides to traverse a greater extent of atmosphere before they arrive at the eye of the observer. On determining by experiment the refraction at every altitude from zero to 90°, tables of *Refraction* may be constructed, which will furnish the means of discovering the law of its diminution; but as such a process would be exceedingly tedious, and likewise subject to lead to erroneous results on account of the inevitable errors of observation, it is found more convenient to assume some hypothesis for a basis of calculation, and to verify the results which it leads to by comparing them with observation. In regard to media which may be said to be permanent, such, for instance, as water and glass, the determination of the refraction is not attended with great difficulty; but the circumstances are greatly altered when we come to make experiments on the atmosphere. In this case the difficulty arises from the incessant changes which the atmosphere is undergoing relatively to its refringent powers; changes which it is impossible for the observer fully to appreciate, inasmuch as he can only determine its physical state within a short distance of the earth, while that of the upper strata remains wholly unknown to him. The refringent power of the atmosphere is affected by its density and temperature. The effects of the humidity are insensible; for the most accurate experiments seem to prove that the watery vapours diminish the density of the air in the same ratio as their refractive power is greater. It is therefore only necessary, even in delicate experiments, to have regard to the state of the barometer and thermometer at the time the observation is made. At a medium density, and at the temperature of melting ice, it was found by Biot and Arago, from a great number of exact experiments, that at any altitude between 10° and the zenith the refraction is very nearly represented by the formula $r = 60''{\cdot}6 \tan. (Z - 3{\cdot}25 \times r)$, in which r is the refraction corresponding to a given zenith distance Z. With the exception of the numerical co-efficients, this formula was first given by Bradley; but whether it was deduced from theory by that great astronomer, or was only empirical, is uncertain. Bradley's formula was $r = 57''$ tan. $(Z - 3 \times r)$. When the direction of the luminous rays makes a smaller angle than 10° with the horizon, it becomes indispensable to take into account, in the calculation of the refraction, the law of the variation of the density of the atmosphere at different altitudes; a law which is subject to incessant variation, from the operation of winds, and other causes which agitate the atmosphere, as well as the decrease of temperature in the superior regions. For this reason all astronomical observations which have not refraction directly for their object, or which are by their nature independent of its influence, are made at an elevation exceeding 10°. For lower altitudes, it is to be feared that no theory will ever be found sufficiently exact to entitle the observations to much confidence.

Theoretical Astronomy.

First observations of refraction.

The existence of the atmospherical refraction was not unknown to the ancient astronomers; but it is only in modern times that the subject has been studied with the requisite care to admit of its influence being calculated in the reduction of observations. Ptolemy does not allude to the subject in the *Almagest*, but he has given a sufficiently exact idea of it in his work on *Optics*. He mentions experiments made to ascertain how far a ray of light is bent from its rectilinear course in passing from air into glass and water; and observes that the astronomical refraction brings a star nearer to the zenith, and that it is feebler in proportion as the star is more elevated. He likewise indicates a method of measuring its effects, although he does not seem to have attempted to practise it. The same notions, but in a less precise form, were reproduced in the *Optics* of Alhazen. Walther began to estimate the effects of refraction near the horizon; and Tycho, a century after, found the means of measuring them with greater accuracy, and was thereby enabled to construct a table. Tycho estimated the horizontal refraction at 34′, and supposed it to vanish at the altitude of 45°; which proves that his ideas on the subject were less accurate than those of Ptolemy, who says expressly that it vanished only at the zenith. Dominic Cassini was the first who proposed an hypothesis for calculating the refraction at any altitude; and he computed a table, which was published in 1662. Since that time the subject of refraction has been investigated, theoretically and practically, with the most scrupulous and delicate attention, and tables constructed to exhibit its amount at every altitude, and at the different seasons of the year. (See *Mécanique Céleste*, tom. iv. p. 231; Mr Ivory's Paper in the *Phil. Trans.* for 1823, p. 409; Delambre, *Astronomie du xviii. Siècle*, p. 774.)

The refringent power of the atmosphere gives rise to a number of curious phenomena. When the sun appears in

Oval appearance of the sun and moon in the horizon.

the horizon, the rays of light which issue from the extremities of his vertical diameter are refracted unequally on account of the difference of altitude, so that the disk, at other times circular, then assumes an oval appearance; and on measuring the horizontal and vertical diameters by means of the micrometer, the former is sometimes found to exceed the latter by four or five minutes of a degree. This effect is particularly remarkable when the sun is observed at his rising or setting from the top of a mountain, or an elevation near the sea-shore, in which cases the difference of the two diameters sometimes, in particular states of the atmosphere, amounts to upwards of 6′, or a fifth of the whole apparent diameter of the sun. In the case of the moon this oval appearance is seldom so perceptible; for unless she happens to be exactly full, or in opposition, at the same time that she is in the horizon—and this can rarely be the case—the defect of the illumination of her disk reduces her figure to those rounder but somewhat irregular shapes which it often exhibits. The horizontal refraction being equal to the apparent diameter of the sun or moon, it happens also that either of these luminaries, and consequently any other of the celestial bodies, may be entirely visible above the plane of the horizon, when in fact it has set below it. A curious instance of this was observed at Paris in 1750. The moon rose eclipsed, while the sun, whose place at the time of a lunar eclipse is diametrically opposite to that of the moon, still appeared above the horizon. Another phenomenon occasioned by the refraction of the atmosphere is the appearance of the moon when she is eclipsed, or immersed in the earth's shadow, and consequently receives no light directly from the sun. On these occasions her disk continues distinctly visible, and is of a dusky red colour, exhibiting the appearance of tarnished copper, or iron nearly red-hot. This phenomenon occasioned great perplexity to the ancient astronomers who were unacquainted with the refractive powers of the atmosphere; and some of them ascribed it to the native light of the moon, in virtue of which she continues visible when hid from the sun's rays. Plutarch ingeniously supposed it to be occasioned by the light of the stars reflected from the dark surface of the moon; but the quantity of this light is greatly too small to produce the effect in question. It is now explained by the scattered beams of light bent into the earth's shadow by refraction in their passage through the atmosphere.

The refraction of the rays of light in traversing the earth's atmosphere is the cause of *Twilight*, which sensibly lengthens the duration of the day, and prevents a sudden transition from light to darkness on the disappearance of the sun. When the sun is more than 33′ below the horizon, the refraction is not powerful enough to bring his rays sufficiently near the earth to reach our eyes; they pass over our heads, and are irregularly reflected by the molecules of the atmosphere. By this means a portion of the celestial vault is enlightened, while the sun is invisible. This illumination of the upper regions is called the twilight. It commences as soon as objects can be distinguished before sun-rise, and terminates when they cease to be visible after the sun has set. The time, however, at which the twilight commences and terminates cannot be assigned with any degree of precision. It is generally supposed to be limited by the depression of the sun 18° below the horizon. Lacaille found the limit in the torrid zone to be between 16° and 17°. According to Lemonnier, it varies in France between 17° and 21°. The duration of the twilight will evidently be longer or shorter according as the inclination of the plane of the sun's orbit to the horizon is more or less oblique.

To assign the time at which it is a maximum or minimum, or of a given length at a given latitude, is a problem of pure geometry, which has been frequently solved since the time of the Bernoullis.

Scintillation of the stars.

The scintillation or twinkling of the stars is another phenomenon produced by certain modifications of atmospherical refraction. The atmosphere is at all times more or less agitated; and on this account the clusters of molecules of which it is composed are constantly undergoing momentary compressions and dilatations, which occasion minute differences of refraction, and consequent changes in the directions of the luminous rays. The minute and rapid variations thus occasioned in the apparent places of the stars produce the twinkling or tremulous appearances which, in certain states of the atmosphere, particularly on the approach of rain after a long drought, are very remarkable. The agitations of the atmosphere are manifest to the eye in the tremulous motion of the shadows cast from high towers, and in looking at objects through the smoke of a chimney, or over beds of hot sand. The scintillation of the planets is much less than that of the stars. This proceeds from the magnitude of their disks, which, although apparently very small, are still far greater than those of the fixed stars, and indeed so considerable, that the accidental variations in the directions of the rays of light are too minute to displace them entirely. The borders of their disks are affected only by a slight undulation; whereas the stars, which are merely brilliant points of insensible magnitude, undergo a total displacement.

Horizontal moon.

The apparent enlargement of the sun and moon in the horizon is an optical illusion, connected in some measure with the atmosphere, of which various explanations have been given since the time of Ptolemy. According to the ordinary laws of vision, the celestial bodies, particularly the moon, which is nearest to the earth, ought to appear largest in the meridian, because their distance is then less than when they are near the horizon; and yet daily experience proves that the contrary takes place. To an observer placed at E (fig. 10), the visual angle subtended by the moon in the horizon at M is somewhat less than that under which she appears in the zenith at O; and this fact, a consequence indeed of her circular motion, is proved by accurate measurements of her diameters in those circumstances by the micrometer. The mean apparent diameter of the moon, at her greatest height, is 31′ in round numbers, but in the horizon she seems to the eye two or three times larger. The commonly received explanation of this phenomenon was first given by Descartes, and after him by Dr Wallis, James Gregory, Malebranche, Huygens, and others, and may be stated as follows. The opinion which we form of the magnitude of a distant body does not depend exclusively on the visual angle under which it appears, but also on its distance; and we judge of the distance by a comparison with other bodies. When the moon is near the zenith there is no interposing object with which we can compare her, the matter of the atmosphere being scarcely visible. Deceived by the absence of intermediate objects, we suppose her to be very near. On the other hand, we are used to observe a large extent of land lying between us and objects near the horizon, at the extremity of which the sky begins to appear; we therefore suppose the sky, with all the objects which are visible in it, to be at a great distance. The illusion is also greatly aided by the comparative feebleness of the light of the moon in the horizon, which renders us in a manner sensible of the interposition of the atmosphere. Hence the moon, though seen under nearly the same angle, alternately appears very large and very small. Desaguliers illustrated the doctrine of the horizontal moon on the

Fig. 10.

Theoretical Astronomy.

supposition of our imagining the visible heavens to be only a small portion of a spherical surface, as *mnop* (fig. 10), in which case the moon, at different altitudes, will appear to be at different distances, and therefore seem to vary in magnitude, as at *m*, *n*, *o*. It is evident, however, that this affords no explanation of the phenomenon; for why does the sky, it may be asked, appear to be a smaller segment than a hemisphere? In the solution of this question the whole difficulty is contained.

Fig. 10.

It may be remarked that these illusions disappear as soon as the intermediate objects are concealed from view. They may be destroyed by regarding the moon through a tube, which permits her disk alone to be seen, and in this manner she will appear no larger at the horizon than near the zenith. The same effect may be produced by viewing her through a smoked glass, because the dark tint permits only the luminous object to be seen, and conceals all the rest. The only precaution necessary to be observed in making this experiment, is to place the eye in such a position that the surrounding bodies may not be visible.

CHAP. II.

OF THE SUN.

SECT. I.—*Of the Apparent Circular Motion of the Sun in the Ecliptic, and Position of the Ecliptic in Space.*

The consideration of the diurnal motion common to all the celestial bodies, and the succession of day and night resulting from it, forms the first object of astronomy. The second is to pass from the diurnal motion of the sphere to the proper motion of the sun, and from the vicissitudes of the day to the seasons of the year. The sun, as has already been remarked, is constantly shifting his place among the stars. If we observe the altitude of any star, or group of stars, above the eastern horizon at sun-set, we shall find, on making the same observation a few days afterwards, that its elevation is considerably increased, and that it has approached nearer to the meridian. At the end of three months it will appear at sun-set on the meridian, and from that time continue to advance nearer and nearer to the sun, till it is at last concealed by the splendour of his rays. After remaining for some time invisible, it will again make its appearance in the morning to the westward of the sun, and its distance from him will continue to increase daily, till, at the end of a year, it has made a complete circuit of the sky, and regained the position it occupied at the time of the first observation. The earliest observers explained this phenomenon by supposing the diurnal motion of the sun to be less rapid than that of the stars, in consequence of which he constantly falls behind them. This supposition would be admissible if the sun remained constantly in the plane of the equator; but as he deviates considerably from that plane, on both sides of it, it is infinitely more simple to ascribe to the sun a motion of his own, independent of the diurnal motion, and performed in a contrary direction, in virtue of which he traces an oblique route among the stars.

Sun's course in the heavens.

The oblique path of the sun may be determined by observing the positions of the stars near which he successively passes in the course of the year. The same object is however accomplished with much greater precision by the modern practice of observing his declinations and right ascensions, that is to say, his distances from the equator, and an arbitrary meridian. In this manner his place may be accurately assigned every day; and, by a repetition of similar observations, a series of points will be obtained on the surface of the celestial sphere, which mark out his annual course. The result of constant experience shows, that the declination reaches its maximum on the south side of the equator about the 22d of December, when it amounts to 23·465 degrees. From this time it gradually diminishes till about the 21st of March, when the sun reaches the plane of the equator. At this time the days and nights are of equal length all over the earth, and the instant of time at which the sun's centre is in the equatorial plane is called the instant of the equinox. The sun then appears on the opposite side of the equator, and his declination or meridional altitude continues to increase till about the 22d of June, when he becomes stationary, and then again shapes his course towards the equator. His maximum declination on the north side of the equator is exactly equal to that on the south, amounting to 23°·465. The sun now continues to approach the equator till about the 24th of September, when he again reaches that plane, and a second equinox succeeds. Continuing still to move in the same direction, he declines from the equator southward, till he reaches his former limit about the 22d of December, after which he resumes his former course.

Theoretical Astronomy

The two small circles of the sphere, parallel to the equator, which pass through the two points where the declination is great, are called the *Solstices*, or the *Tropics*; that on the northern hemisphere is called the *Tropic of Cancer*, and the other is called the *Tropic of Capricorn*. These two parallels, which mark the extreme limits of the sun's declination, are, as has just been stated, equally distant from the equator, with regard to which the variations of declination on either side are perfectly symmetrical and uniform.

Tropics.

If at the time of the vernal equinox we remark the stars which set in the true west while the sun is rising in the east, and which are then separated from him by a semicircumference, it will be found that the difference of their right ascensions, and the right ascensions of those which have precisely a similar situation relatively to the sun at the time of the autumnal equinox, is exactly 180°. It follows, therefore, that the solar orbit intersects the equator in two points diametrically opposite; but we have seen that its northern and southern declinations are equal; hence the orbit projected on the sphere must be a great circle, provided it lies wholly in the same plane. Whether this is the case or not it will be easy to prove by means of a few observations, in the following manner.

Let AQ (fig. 11) be the equator, AE the orbit of the sun, PSM, PTN two circles of declination, drawn through any two points S and T of the orbit. If the sun's path is confined to a plane, then AE must be a great circle, and we shall have the equation $\sin. AM = \frac{\tan. MS}{\tan. MAS}$, according to the well-known properties of spherical triangles. Let the cotangent of the unknown but constant angle $MAS = n$, the declinations $MS = D$, $NT = D'$, the right ascensions $AM = Æ$, $AN = Æ'$; then, according to the above formula, we must have $\sin. Æ = n \tan. D$, and $\sin. Æ' = n \tan. D'$, at whatever points of the orbit S and T may be situated. From these two last equations there result also $\cos. Æ = \sqrt{1 - n^2 \tan.^2 D}$, $\cos. Æ' = \sqrt{1 - n^2 \tan.^2 D'}$, which, being substituted in the trigonometrical formula $\sin. (Æ' - Æ) = \sin. Æ' \cos. Æ - \cos. Æ' \sin. Æ$, we shall have $\sin. (Æ' - Æ) = n \tan. D' \sqrt{1 - n^2 \tan.^2 D} - n \tan. D \sqrt{1 - n^2 \tan.^2 D'}$. The observations of the meridional altitudes will give the declinations D and D'; and the difference of right ascensions, Æ'—Æ, will be found by comparing the time of the sun's culmination, or transit over

Fig. 11

Theoretical Astronomy.

the meridian, with that of a star. If, therefore, it is found that, by assigning a certain constant value to n, this equation will satisfy all the observations, combined by pairs, of the sun's right ascensions and declinations, it will follow that the plane determined by any two points in the sun's course and the point in which it intersects the equator, has always the same inclination to the equator; in other words, all the planes so determined are identical.

Now the observations of the sun's right ascensions and meridional altitudes, which have been made daily during so great a number of years, and under so many different meridians, are found to conform entirely with the preceding formulæ: they therefore furnish so many proofs that the projection of the sun's orbit is a great circle of the celestial sphere, and that the orbit itself is wholly confined to the same plane.

Ecliptic.

The great circle which the sun describes in virtue of his proper motion is called the *Ecliptic*. It has received this name from the circumstance that the moon, during eclipses, is either in the same plane or very near it. These phenomena can in fact only happen when the sun, earth, and moon are nearly in the same straight line, and, consequently, when the moon is in the same plane with the earth and the sun. The angle formed by the planes of the ecliptic and equator, and which is measured by the arc of a circle of declination intercepted between the equator and tropic, is called the *Obliquity of the Ecliptic*. The two points in which the equator and ecliptic intersect each other are called the *Equinoctial Points:* they are also denominated the *Nodes of the Equator;* and the straight line conceived to join them is the *Line of the Equinoxes*, or the *Line of the Nodes*. The node through which the sun passes on coming from the south to the north of the equator is called the *Ascending Node*, and is usually distinguished by the character ☊; the opposite node is the *Descending Node*, and is marked by ☋. A straight line passing through the centre of the earth, perpendicular to the plane of the ecliptic, is called the *Axis*, and the points in which its prolongation meets the sphere are called the *Poles, of the Ecliptic;* these denominations being analogous to those of the axis and poles of the equator. The two small circles of the sphere which pass through the poles of the ecliptic, and are parallel to the equator, are called the *Polar Circles*.

Nodes.

Signs of the zodiac.

The ecliptic has been divided by astronomers, from time immemorial, into twelve equal parts, called *Signs*, each of which consequently contains 30 degrees. The names and symbols by which they are characterized are as follows:—

North of the Equator.		South of the Equator.	
Aries	♈	Libra	♎
Taurus	♉	Scorpio	♏
Gemini	♊	Sagittarius	♐
Cancer	♋	Capricornus	♑
Leo	♌	Aquarius	♒
Virgo	♍	Pisces	♓

In each of these signs the ancients formed groups of stars, which they denominated *asterisms*, *constellations*, *animals* (ζωδια), not confined to the ecliptic, but included within an imaginary belt, extending 8° on each side of it, to which they gave the name of *Zodiac* (ζωδιακος κυκλος, *circle* or *zone of the animals*). The term *sign* is now employed only to denote an arc of 30°, and will probably soon be banished entirely from the astronomical tables. It is already confined to the tables of the planets. Thus, to denote that the longitude of a planet is 276° 12′, it is usual to write 9ˢ 6° 12′. Formerly it was usual to employ the characteristic symbol, and to write ♑ 6° 12′, meaning that the planet was 12′ in the 6th degree of Capricornus, or the tenth sign. This inconvenient practice is now laid aside, and the signs, when they are employed, are simply distinguished by the ordinal numbers.

Theoretical Astronomy.

As the greater part of the celestial phenomena connected with the planetary system take place either in the ecliptic or in planes not greatly inclined to it, it is found to be most convenient to refer the positions of the planets, and frequently those of the stars also, to that plane. The first point of Aries, which is the technical expression for the intersection of the ecliptic and equator, or the place of the sun at the vernal equinox, is assumed as the origin from which the degrees of the equator, as well as of the ecliptic, are counted from west to east, or in the direction of the sun's annual motion. The angular distance of the sun from this point is called his *Longitude;* and the longitude of a star is the arc intercepted on the ecliptic between the same point and a great circle passing through the star perpendicular to the ecliptic. The arc of this circle intercepted between the star and the ecliptic, or, which is the same thing, the complement of the star's distance from the pole of the ecliptic, is called the *Latitude* of the star; so that longitude and latitude are with regard to the ecliptic what right ascension and declination are with regard to the equator. Thus, let O♈Q (fig. 12) be the equator, I♈L the ecliptic, P and E the north poles of these two circles respectively, and S the place of a star. Having drawn through the pole of the ecliptic and the star the great circle ESM perpendicular to the ecliptic in M, then ♈M is the longitude of S, counted on the ecliptic from the vernal point ♈ towards the east; and SM, the distance of the star from the ecliptic, is its latitude; and for this reason all great circles passing through the poles of the ecliptic are called *Circles of Latitude*. The place of a star is thus determined by its longitude ♈M, and its latitude SM, as well as by its right ascension ♈R, and its declination SR; and when the angle L♈Q is known, it is easy to pass from the one system of co-ordinates to the other by means of the formulæ of spherical trigonometry. These formulæ are of constant use, for it is the declinations and right ascensions only which are directly observed.

Fig. 12.

Obliquity of the ecliptic.

The plane of the sun's orbit will be determined completely when its inclination to the equator and the position of the line of the nodes in space have been made known by observation. The declination of the sun twice a year, namely, at the summer and winter solstice, is equal to the obliquity of the ecliptic; whence, if the solstice happened exactly at mid-day, the obliquity would be given directly by an observation of his meridional altitude. This circumstance, however, can happen only for one terrestrial meridian; but as the declination of the sun when he approaches the tropics varies little from one day to another, his greatest observed declination will be a very near approximation to the obliquity, at whatever part of the earth the observation may have been made. It is easy, however, to correct the error which results from the observation being made on a meridian different from the solstitial colure. Taking an example from Woodhouse, let us suppose the sun's declination to be observed on three successive days (the 20th, 21st, and 22d of June), and found to be on these days respectively,

23° 27′ 37″, 23° 27′ 41″, 23° 27′ 20″;

then it is obvious, that if the middle observation gave the greatest inclination exactly, the other two would differ from it equally, which they do not. The maximum declination is therefore a quantity somewhat different from 23° 27′ 41″; and it is easy to conclude, from the inspection of the numbers, that it is nearer to 23° 27′ 41″ than to either of the other two. It is obvious, therefore, that that observation must have been made within 12 hours of the

Theoretical Astronomy

time when the sun was exactly in the solstitial point. In order to form an exact notion of the amount of error which may possibly arise from this circumstance, let S (fig. 13) be the place of the sun at the time of the observation, and X the true but as yet unknown solstitial point, and S s, X x meridional arcs intersecting the equator in s and x. The arc S X must be less than 30′, for in 12 hours the variation of the sun's longitude does not exceed an arc of that magnitude. Suppose it 30′: then, by Napier's rules,

Plate LXXVII. Fig. 13.

$$\text{sin. S } s = \text{sin. } \curlyvee \times \text{sin. S } \curlyvee,$$
$$\text{and sin. X } x = \text{sin. } \curlyvee \times \text{sin. X } \curlyvee;$$

whence, on eliminating sin. $\curlyvee$, and observing that sin. X $\curlyvee$ = sin. 90° = 1, we shall have

$$\text{sin. X } x = \frac{\text{sin. S } s}{\text{sin. S } \curlyvee} = \frac{\text{sin. S } s}{\text{cos. S X}}.$$

By taking, according to the observation, S s = 23° 27′ 41″, and S X = 30′, we shall find from the logarithmic tables X x = 23° 27′ 44″·5. It will be observed that 30′ is the maximum error in longitude; if instead of 30′ it had been supposed only 3′, the corresponding error in declination would have amounted only to 0″·035. In the example chosen, the error of longitude is about 20′, whence the error of declination is 1″·5 nearly, and consequently the resulting obliquity differs little from 23° 27′ 42″·5. This result is, however, to be understood of the *apparent* obliquity, which is subject to slight variations, depending on the longitudes of the moon's nodes: the *mean* obliquity, deduced from the comparison of a great number of observations, both of the summer and winter solstice, may be regarded as amounting to 23° 27′ 41″ at the commencement of the year 1830. We shall see, when we come to speak of the *Nutation*, in what the difference between the apparent and mean obliquity consists. Theoretical Astronomy

When the mean value of the obliquity of the ecliptic, as determined by the delicate instruments of the present day, is compared with that given by ancient observations, it appears to have undergone a progressive diminution, and is always greater as the observation is more remote The ancient observers were not, indeed, possessed of the means of determining an element of this sort with great precision; but as all the observations recorded in history agree in making the obliquity greater in former times than it is now, the probability is almost infinite that the angle formed by the planes of the equator and ecliptic has really diminished; for, had the differences of the values assigned to it arisen solely from errors of observation, they would have been in excess and defect indifferently, instead of being, as they are, uniformly in excess. The various observations and traditions by which the progressive diminution of the obliquity is confirmed have been collected by Bailly; in the following table we have inserted those which appear to be the best authenticated, and have added the results of some recent observations, from which can be deduced the present value of the obliquity, and the rate of its diminution.

Year.	Name of Observer.	Obliquity.			Year.	Name of Observer.	Obliquity.		
Before Christ.					After Christ.				
200	Eratosthenes, confirmed by Hipparchus and Ptolemy	23°	51′	15″	1690	Flamsteed	23°	28′	48″
160	The Chinese	23	45	52	1703	Bianchini	23	28	35
					1736	Condamine	23	28	24
					1743	Cassini de Thury	23	28	26
After Christ.					1750	Lacaille	23	28	19
					1755	Bradley	23	28	15
827	Arabians at Bagdad	23	33	52	1756	T. Mayer	23	28	16
880	Albategnius	23	35	40	1769	Maskelyne	23	28	10
1150	Almansor	23	33	30	1780	Cassini	23	27	54
1278	The Chinese	23	32	12	1800	Maskelyne	23	27	56·6
1437	Ulugh Beigh	23	31	58		Piazzi	23	27	56·3
1490	Walther	23	29	47		Delambre	23	27	57

Secular rate of diminution.

Although the comparison of these observations with one another gives very discordant results relatively to the law according to which the obliquity varies, their totality places the fact of its progressive diminution beyond all manner of doubt. Lacaille, who was followed by the greater number of astronomers, estimated the diminution of 44″ in a hundred years; a result to which he was led chiefly by a comparison of his own observations with those of Walther. Lalande, after comparing an immense number of modern observations with those of the 17th, 16th, and 15th centuries, and also with those of the Arabians and Chinese, found the secular diminution to be 50″. Bessel, rejecting the ancient observations as too uncertain, and comparing those only which have been made since the time of Bradley, has fixed the secular diminution at 45″·7, which differs inconsiderably from the determination of Lacaille. It cannot yet be determined by observation whether this diminution is uniform, or accelerated, or retarded; but so slow is the rate at which it proceeds, that it may, without any sensible error, be regarded as uniform for many centuries to come.

The gradual diminution of the obliquity of the ecliptic might lead us to suppose that a time will ultimately arrive when that plane will coincide with the equator, and the earth be deprived, in consequence, of the agreeable vicissitude of the seasons. But the theory of universal gravitation, which has revealed the cause of the diminution, has also shown that there are certain limits which the angle of the two planes can never exceed, and between which it must continue for ever to oscillate. Geometers have not yet ventured to assign the precise extent of these limits, but their existence is certain; and the planes of the ecliptic and equator, which have been approaching to each other during the last 2000 years, will, in the course of some thousands of years more, begin to recede.

Displacement of the ecliptic.

In what has yet been said respecting the diminution of the obliquity of the ecliptic, no fact has been mentioned from which it can be inferred, whether the phenomenon is

Theoretical Astronomy.

occasioned by the displacement of the plane of the ecliptic or that of the equator. This question may also be decided by a comparison of modern with ancient observations; for it is evident, that if the inclination of these two planes becomes less, the stars which are situated between them, particularly those near the solstitial colure, will appear to approach to that plane which changes its position; so that if the ecliptic is displaced, the latitudes of those stars will be diminished, or their declinations if the displacement belongs to the equator. It was first observed by Tycho, and the observation has been confirmed by succeeding astronomers, that the latitudes of the southern stars situated near the solstitial colure, that is, of those stars whose longitudes are nearly 90°, have diminished upwards of 20′ since the time of Hipparchus and Ptolemy, while the latitudes of the northern stars have undergone a corresponding augmentation. From this fact it is proved that the diminution of the obliquity is occasioned by the displacement of the ecliptic; and theory has shown that the cause of the displacement is the action of the planets, particularly of Jupiter and Venus, on the earth, by virtue of which the plane of the earth's orbit is drawn nearer to the planes of the orbits of these two planets. This, however, though by far the most considerable, is not the sole cause of the phenomenon; for theory also shows that a slight motion of the plane of the equator is produced by the attraction of the sun and moon, but so very minute that its effects will only become appreciable after a long series of ages.

Precession of the equinoxes.

After determining the inclination of the plane of the ecliptic to that of the equator, the only element requisite to fix its position absolutely in space, is the situation of the straight line formed by its intersection with that plane, that is to say, the line of the nodes. The longitudes of the stars, as has already been mentioned, are counted on the ecliptic from the vernal equinox; and therefore, if the line of the equinoxes, which is the same as the line of the nodes, is invariable, the longitude of any star will always be the same, whatever interval of time may elapse between two observations of that longitude. But on comparing the actual state of the heavens with the observations recorded by ancient astronomers, it is perceived that the longitudes of all the stars are considerably increased; whence we must infer, either that the whole firmament has advanced in the order of the signs, or that the equinoctial points have gone backwards, or retrograded. The latter supposition is infinitely the more probable; for it is inconceivable that the innumerable multitude of stars should have a common motion relatively to points which depend solely on the motion of the earth. The phenomenon is therefore to be explained by attributing to the equinoctial points a retrograde motion from east to west, in consequence of which, the sun, whose motion is direct, arrives at them sooner than if they remained at rest; and therefore the equinoxes, spring, autumn, and the other seasons, happen before the sun has completed an entire circuit. On this account the motion has been denominated the *Precession of the Equinoxes*. As this motion is extremely slow, its exact amount can be discovered only by a comparison of observations separated from each other by long intervals of time; but the imperfection of instruments prior to the sixteenth century renders the ancient observations of little authority where quantities so minute are concerned, and therefore some discrepancies may be expected in the different determinations of the amount of the precession. The comparison of modern observations with those of Hipparchus gives its annual amount equal to 50⅔ seconds, and with those of Ptolemy somewhat greater. The mean result of the observations of Tycho, compared with those of Lacaille, gives 50″⅛. On comparing modern observations with one another, we find 50″·06. Delambre, in his solar tables, supposes the annual precession to be equal to 50″·1. According to this estimate the equinoctial points go backwards at the rate of one degree in 71·6 years nearly, and therefore will make a complete revolution of the heavens in about 25,868, or nearly 26 thousand years.

Theoretical Astronomy.

The discovery of the precession of the equinoxes is generally attributed to Hipparchus, who, on comparing his own observations with those of Timocharis, more ancient by 160 years, perceived that in this interval the longitudes of the stars had been augmented by about two degrees. It would seem, however, from many proofs collected by Bailly, that this motion, slow as it is, was known to all the ancient nations who cultivated astronomy, long before the time of Hipparchus. It is indeed easy to conceive, from the great attention which they gave to the heliacal risings of the remarkable stars, that they might observe a gradual change of the seasons at the occurrence of these phenomena, from which they would necessarily be led to conclude a variation of the star's longitude. In consequence of this regression of the equinoctial points, the sun's place among the zodiacal constellations at any given season of the year is now greatly different from what it was in remote ages. Some time prior to Hipparchus, the first points of Aries and Libra corresponded to the vernal and autumnal equinoxes; those of Cancer and Capricorn to the summer and winter solstices: at present these constellations have separated 30 degrees from the same points of the ecliptic. The vernal equinox now happens in the constellation Pisces, the summer solstice in Gemini, the autumnal equinox in Virgo, and the winter solstice in Sagittarius. Astronomers, however, still count the signs from the vernal equinox, which, therefore, always corresponds to the first point of the *Sign* of Aries. On this account it is necessary to distinguish carefully between the *Signs* of the Zodiac, which are fixed with regard to the equinoxes, and the *Constellations*, which are movable with respect to those points.

Physical cause of the precession of the equinoxes.

The diminution of the obliquity of the ecliptic arises from the displacement of the ecliptic itself; the precession of the equinoxes is, on the contrary, occasioned by the continual displacement of the plane of the terrestrial equator. This displacement results from the combined action of the sun and moon (for the influence of the planets amounts only to a fraction of a second, and is consequently scarcely sensible,) on the mass of protuberant matter accumulated about the earth's equator, or the matter which forms the excess of the terrestrial spheroid above its inscribed sphere. The attracting force of the sun and moon on this shell of matter may be resolved into two; one parallel to the plane of the equator, the other perpendicular to it. The tendency of this last force is to diminish the angle which the plane of the equator makes with that of the ecliptic; and if the earth had no motion of rotation, it would soon cause the two planes to coincide. In consequence, however, of the rotatory motion of the earth, the inclination of the two planes remains constant; but the effect produced by the action of the force in question is, that the plane of the equator is constantly shifting its place, in such a manner that the line of the equinoxes advances in the direction of the diurnal motion, or contrary to the order of the signs, its pole having a slow angular motion about the pole of the ecliptic, so slow indeed, that it requires nearly 26,000 years to complete its revolution.

Nutation.

If the sun and moon moved in the plane of the equator, there would evidently be no precession; and the effect of

their action in producing it varies with their distance from that plane. Twice a year, therefore, the effect of the sun in causing precession is nothing; and twice a year, namely at the solstices, it is a maximum: on no two successive days of the year is it exactly the same, and consequently the regression of the equinoctial points, which results from the sun's action, must be unequable. On this account the obliquity of the ecliptic is subject to a semi-annual variation; for the sun's force, which tends to produce a change in the obliquity, is variable, while the diurnal motion of the earth, which prevents the change from taking place, is constant. Hence the plane of the equator is subject to an irregular motion, which is technically called the *Solar Nutation*. The existence of the solar nutation is, however, only a deduction from theory, for its amount is too small to be perceptible to observation; but a similar effect of the moon's action is sufficiently appreciable, and was, in fact, discovered by Dr Bradley before theory had indicated its existence. Its period, however, is different, and depends on the time of the revolution of the moon's nodes, which is performed in 18 years and about 7 months. During this time the intersection of the lunar orbit with the ecliptic has receded through a complete circumference; and the inequality of the moon's action will consequently, in the same time, have passed through all its different degrees. Bradley observed that the declinations of the stars continued to augment during nine years, that they diminished during the nine years following, and that the greatest change of declination amounted to 18″. He remarked further, that this motion was connected with an irregularity of the precession of the equinoxes, which followed exactly the same period; whence he concluded that the motion of the poles of the equator, occasioned by this vibration of its plane, was not confined to the solstitial colure. A series of observations on stars differently situated proved that all the phenomena could be explained on the hypothesis that the pole of the equator describes in 18 years a small circle of 18″ diameter, contrary to the order of the signs; or that the axis of the earth, following the circumference of this circle, describes the surface of a cone, the axis of which forms with its side an angle of 9″. This apparent vibratory motion is significantly denominated the *Nutation of the Earth's Axis*.

Path described in space by the pole of the equator.

In consequence of the two motions which occasion the precession and the nutation, the true path of the pole of the equator round that of the ecliptic is an epicycloidal curve, which will be understood by referring to fig. 14. Let E be the pole of the ecliptic, round which the pole of the equator P describes, in virtue of the precession, and in a direction contrary to the order of the sines, the circle PQR, of which the radius EP is equal to the obliquity of the ecliptic, or the mean distance of the two poles. While P, the mean place of the pole, moves in the circle PQR, with a velocity equal to the regression of the equinoctial points, or at the rate of 50″·1 a year, the *true* pole *p* describes at the same time round P a small circle of 18″ diameter in the same direction *pqr*. The true path of the pole is therefore along the circumference of a circle *pqr*, the centre of which retrogrades on the circumference of another circle, and consequently moves in an epicycloid *abcdefg*, the curve which results from the composition of the two motions. Suppose the mean pole at Q, the true pole at *a*, and *a*Q=9″. In the course of nine years the mean pole will have retrograded from Q to R, making QR=9×50″·1, while the true pole will have accomplished a semi-revolution in its circle. It will therefore be at *c* (R*c* being=9″), and have described the epicycloidal arc *abc*, the greatest distance of which from the circle PQR is at *b*, and equal to 9″. At the end of the following nine years the mean pole has retrograded from R to S, or 9×50″·1, and the true pole has returned to the same point *a* of its epicycle; it will therefore be found at *e*, S*e* being =9″. In this interval it has necessarily been within the circle PQR, its greatest distance from which at *d* is 9″, so that in 18 years it has traced the curve *abcde*. But *ac* = QR + *a*Q + R*c* = 9 × 50″·1 + 18″ = 7′ 49″, and *ce*=RS—R*c*—S*e* = 9×50″·1—18″ = 7′ 13″. From *a* to *c* the motion of the true pole in the epicycle is in the same direction as that of the mean pole; from *c* to *e* it is in an opposite direction, but as it is always much slower, being only about 3″ in a year, while that of the mean motion is 50″·1, the true motion which results from the combination of both will always be in the direction *ce*, and at *d* its velocity will be equal to their difference. At *b* and *d* the difference between the latitudes of the true and mean pole is a maximum, while the difference of their longitudes is nothing; in other words, the correction of the obliquity is greatest when that of the precession vanishes: at *a*, *c*, and *e* the correction of the obliquity vanishes, and that of the precession is a maximum.

Fig. 14.

Pole describes an ellipse.

Dr Bradley remarked that the effects of the nutation would be represented still more accurately by supposing the curve described by the pole of the equator about its mean place to be an ellipse instead of a circle, the transverse and conjugate axes being 18″ and 16″ respectively. This is also confirmed by theory, from which Laplace calculated the semi-axes of the ellipse at 9″·63 and 7″·17. The semi-transverse axis of the ellipse described by the pole in virtue of the sun's action alone does not exceed half a second, and is consequently totally inappreciable. The sensible part of the nutation, therefore, follows exactly the period of the revolution of the nodes of the moon. By 603 observations of Polaris, observed at Dorpat between 1822 and 1838, M. Peters has determined the semi-axis major of the ellipse to be 9″·2361, and gives, for his definitive result, 9″·2231.

It is now easy to see the reason of the distinction drawn above between the *mean* and the *true* or *apparent* obliquity. The mean obliquity is represented by the radius EP of the deferent circle PQR, along the circumference of which the centre of the small circle or ellipse is carried, while the true obliquity is that quantity increased or diminished by the nutation. The calculation of the mean obliquity from the true is performed by the aid of the astronomical tables.

The progressive diminution of the mean obliquity and the nutation of the earth's axis are inequalities distinguished from each other, not only by their being derived from different and distinct causes, but still more by the very great difference of time required for their full development. Almost every other element of the planetary system is affected in a similar manner by inequalities of two kinds, which are distinguished by the terms *secular* and *periodic*. The secular inequalities proceed with extreme slowness, and continue progressive in the same sense during many centuries; while the periodic are much more rapid in their march, and run through the whole period of their changes in comparatively short intervals of time. The inequalities of the first kind are also periodic; but their periods are vastly longer, and may be reckoned by centuries instead of years; and from this circumstance they derive their name of *secular inequalities*.

Sect. II.—*Of the Orbit of the Sun.*

Having now considered the situation of the plane in which the sun is observed to move relatively to the fixed stars, and also the small secular and periodic variations

Theoretical Astronomy.

to which it is subject, we proceed next to inquire into the nature of his orbit, or the curve which he describes on that plane. The means which we have of determining the solar orbit are the observed variations of the sun's angular velocity, and of his distance from the earth; hence two kinds of observations are necessary,—the first, of his daily meridional altitudes, from which, as the inclination of the orbit is known, his angular velocity is easily found; and the second, of his apparent diameter, the variations of which follow the inverse ratio of his distance.

That the angular velocity of the sun's motion in his orbit is not uniform, is obvious from the fact that he remains $7\frac{2}{3}$ days longer in the northern than in the southern signs, or, which is the same thing, that the interval between the vernal and autumnal equinoxes is $7\frac{2}{3}$ days longer than the interval between the autumnal and vernal. It is proved by numerous observations that the sun moves with the greatest velocity when at a point situated near the winter solstice; while at the opposite point of the orbit, or near the summer solstice, his velocity is the least. At the first point the diurnal motion is 1°·01943, and at the second only 0°·95319. It is constantly varying between these two points; and the variation is observed to be nearly proportional to the sun's angular distance from the point of his orbit where his velocity is a maximum or minimum. The mean velocity is 0°·98632, or nearly 59′ 11″, which is the rate of the sun's daily motion about the beginning of April and October.

The point of the solar orbit, which is the most remote from the earth, is called the *apogee* (απο γης, away from the earth); that which is nearest is called the *perigee* (περι γης, near the earth). The same points are also called respectively the superior and inferior *Apsis* of the orbit, and the straight line which joins them is called the *Line of the Apsides.*

Diameter of the sun.

The exact determination of the sun's diameter is a problem which engaged the earliest astronomers, but of which, before the invention of the telescope and micrometer, it was impossible to obtain a solution sufficiently accurate to make known its variations. Archimedes, by an extremely ingenious though imperfect method, demonstrated that it must be included between the limits $\frac{1}{200}$ and $\frac{1}{164}$ of a right angle, that is, between 27′ and 32′ 55″·7. The Egyptians, by observing the time which the sun takes to rise above the horizon, found it to be between a 750th and a 700th part of a circumference, that is, between 28′ 48″ and 30′ 51″·5. Aristarchus of Samos supposed it to be 30′. The precision of modern observations shows that the apparent diameter is greatest about the time of the winter solstice, and least about the summer solstice; but there is some discrepancy among the results of different astronomers with respect to its actual magnitude. According to the tables of Delambre, its greatest value is 32′ 35″·6, and its least 31′ 31″; the mean apparent diameter, or the diameter at the sun's mean distance, is equal to 32′ 2″·9. According to Bessel, the mean diameter is 32′ 1″·80, as derived from 1698 transits, and the result from the Greenwich observations is 1″·84 greater than this.

From these remarks it is obvious, that if the orbit of the sun be a circle, the earth is not situated in the centre of that circle, otherwise the distance of the sun from the earth would remain always the same, which is contrary to fact. It is possible, however, that the variation in his angular velocity may not be *real*, but only apparent. Thus, in fig. 15, let AMPN be the orbit of the sun, C the centre of that orbit, and E the position of the earth at some distance from the centre. It is obvious that P is the sun's perigee, and A his apogee. Now, as the sun's apparent orbit is a circle having the earth in its centre, it is evident that this orbit must be *a*M*p*N, and that the angular motion of the sun will be measured upon that circle. Suppose now that the sun in his apogee moves from A to A′, it is obvious that his apparent or angular motion will be the segment *a a′* of the apparent orbit, considerably smaller than AA′; so that at the apogee the angular motion of the sun will be less than his real motion. Again, let the sun in his perigee move from P to P′, describing a segment precisely equal to the segment AA′. This segment, as seen from the earth, will be referred to *p p′*, which in that case will be the sun's angular motion, evidently considerably greater than his real motion.

Fig. 15.

Theoretical Astronomy.

Hence it is obvious, that even on the supposition that the sun moved equably in his orbit, his angular motion as seen from the earth would still vary, that is, would be smallest at the apogee and greatest at the perigee, and that the angular and real motion would only coincide in the points M and N, where the real and apparent orbits intersect each other. From the figure, it is obvious also that the angular velocity would increase gradually from the apogee to the perigee, and diminish gradually from the perigee to the apogee, which likewise corresponds with observation.

Sun's motion varies.

But if the variation in the angular motion of the sun were owing alone to the eccentric position of the earth within the solar orbit, it is easy to demonstrate that in that case the diminution of his angular velocity would follow the same ratio as the diminution of his diameter. The fact however is, that the angular velocity diminishes in a ratio twice as great as the diameter of the sun does. The variation of the angular velocity cannot then be owing to the eccentricity alone. Hence it follows that the variation of the motion of the sun is not merely apparent, but real, and that its velocity in its orbit actually diminishes as his distance from the earth increases. Two causes, then, combine to produce the variation in the sun's angular velocity; namely, 1. the increase and diminution of his distance from the earth, and, 2. the real increase and diminution of his velocity in proportion to this variation of distance. These two causes combine in such a manner that the daily angular motion of the sun diminishes as the square of his distance increases, so that the product of the angular velocity multiplied into the square of the distance is a constant quantity.

The observation, that the sun's angular motion in his orbit is inversely proportional to the square of his distance from the earth, is due to Kepler. The discovery was made by a careful comparison of the sun's diurnal motion with his apparent diameter, which is inversely proportional to his distance from the earth. Let ASB (fig. 16) be the sun's orbit, E the earth, and S′ the sun. Suppose a line ES joining the centres of the earth and sun to move round along with the sun. It is obvious that when S moves to S′, ES, moving along with it, is now in the situation ES′, having described the small sector SES′. In the same time that S performs one revolution in its orbit, the radius vector ES will describe the whole area ABS inclosed within the sun's orbit. Let SS′ be the sun's angular motion during one day. It is evident that the small sector SES′ is proportional to the square of ES, multiplied by SS′; for the radius vector is the sun's distance from the earth, and SS′ his angular motion. Hence this sector is a constant quantity, whatever the angular motion of the sun be; and the whole area SEA increases as the number of days which the sun takes in moving from S to A. Hence results that remarkable law, first pointed out by Kepler, that *the areas described by the radius vector are proportional to the times of description.* Suppose the sun to describe SS′ in one day, and SA in twenty days; then

Fig. 16.

Describes areas proportional to the times.

Theoretical Astronomy.

the area SES′ is to the area SEA as 1 to 20, or the area SEA is 20 times greater than the area SES′.

The knowledge of these facts enables us to draw upon paper, from day to day, lines proportional to the length of the radius vector of the solar orbit, and having the same relative position. If we join the extremity of these lines, by making a curve pass through them, we shall perceive that this curve is not exactly circular. Let E (fig. 17) represent the earth, and E *a*, E *b*, E *c*, E *d*, E *e*, &c. the position and length of the radius vector during every day of the year; if we join together the points *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *i*, *k*, *l*, *m*, *n*, *o*, by drawing the curve *a e i m* through them, it is obvious that this curve is not a circle, but elongated towards *a* and *i*, the points which represent the sun's greatest and least distance from the earth. The resemblance of this curve to the ellipse induced Kepler to compare them together; and he ascertained their identity, and thus proved that the orbit of the sun is an *ellipse*, having the earth in one of its foci.

Fig. 17.

Having arrived at the knowledge of the true nature of the sun's orbit, it becomes necessary, in the next place, to determine its position on the plane of the ecliptic, that is, to assign the position of the transverse axis, or line of the apsides, with reference to some other straight line given by position on that plane. The line which it is most convenient to assume for this purpose is the line of the equinoxes; and the position of the apsides may be determined from observations of the time which the sun occupies in performing a semi-revolution, counting from different points of his orbit. Thus, if among the observations of the sun's longitude made daily during the course of a year, we compare, two and two, all those which are diametrically opposite, or which differ by 180°, it will be found that the interval between them will be somewhat less than half a year, if the sun, during that interval, has passed through his perigee, or longer if he has passed through his apogee; and that the time between the two observations will differ less from half the time of a whole revolution, in proportion as the sun's place, at the time of the two observations, was nearer to the apsides. If the difference of time between the two observations is exactly half a year, then the place of the apsides would be obtained at once, because the sun must have been in those points when the observations were made. The probability is, however, infinitely small, that this can ever happen exactly; but as the position of the apsides is known very nearly from the diurnal observations of the variation of the sun's angular velocity, the necesssary corrections can easily be supplied by computation.

From the comparison of observations made in different ages, it appears that the position of the apsides is not fixed on the plane of the ecliptic, but that the greater axis of the solar ellipse revolves in the direction of the sun's annual motion. The observations of Hipparchus, compared with those of the present times, show that the apsides have a direct motion at the rate of 65″ in a year. According to the observations of Walther, the longitude of the apogee in 1496 was 93° 57′ 57″; and according to Lacaille, the same element in 1750 was 98° 37′ 28″; whence, dividing the difference by 254, the interval between the two epochs, the annual motion of the line of the apsides amounts to 66″. Delambre found, by the comparison of a great number of modern observations, that the annual motion is 61″·95 a year. The theory of attraction, which, in respect of such slow and minute variations, must be considered as giving more accurate results than can be obtained directly by observation, gives 61″·9 for the yearly progressive motion of the apsides.

In the above determination, the position of the apsides is referred to the line of the equinoxes, and their motion compared with the sun's tropical revolution. But if we wish to determine their motion with reference to the fixed stars, it is necessary to have regard to the retrograde movement of the equinoctial points; for it is obvious, that if the line of the equinoxes is not fixed, the displacement of the apsides with respect to the stars will be increased or diminished by the whole amount of its motion, according as the two motions are in the same or opposite directions. Now the motion of the line of the apsides is direct, and has just been stated to amount to 61″·9 in a solar year; that of the equinoxes is, on the contrary, retrograde, and amounts to 50″·1 in the same time. Hence the displacement of the apsides, with reference to a star or fixed point in the ecliptic, is 61″·9 — 50″·1 = 11″·8 a year, in the direction of the sun's annual motion. The time, therefore, in which the solar perigee completes a revolution in the heavens, or returns to the same star, is $\frac{360°}{11''.8}$, equal nearly to 110,000 years.

Theoretical Astronomy.

Since the greater axis of the solar ellipse has a progressive motion on the plane of the ecliptic, it forms a variable angle with the line of the equinoxes, and at distant epochs will coincide with that line, or be perpendicular to it. The epochs at which these phenomena happen may be easily found by simple proportions, when the longitude of the perigee at any given time, and its annual motion, are known. According to the observations of Lacaille, already quoted, the longitude of the perigee in 1750 was 278° 37′ 28″; but when the longitude of the perigee was 270°, the greater axis of the solar ellipse must have been perpendicular to the line of the equinoxes. The difference of these two longitudes is 8° 37′ 28″, and the number of years requisite to describe that arc, at the rate of 61″·9 annually, is $\frac{8° 37' 28''}{61''.9}$ = 500 years nearly; whence the major axis was perpendicular to the line of the equinoxes in the year 1250, when the perigee of the orbit coincided with the winter solstice.

Suppose it were required to assign the epoch at which the major axis coincided with the line of the equinoxes. At the occurrence of this phenomenon the longitude of the perigee was 180°, consequently from that time to 1750 the perigee had advanced 278° 37′ 28″ — 180° = 98° 37′ 28″. Now $\frac{98° 37' 28''}{61''.9}$ = 5735; therefore 5735 is the number of years intervening between the occurrence of the phenomenon and 1750. Hence about 4000 years before the commencement of our era, the transverse axis of the solar orbit coincided with the line of the equinoxes; and it is a singular coincidence that this epoch is considered by chronologists to be that of the beginning of the world, or, to speak more correctly, of the first traces of the existence of the human race; for numerous physical circumstances attest that the earth itself has existed during an infinitely longer period. The same phenomenon will again occur when the longitude of the perigee shall have reached 360°, or become zero; and by calculating as above, this will be found to take place in the year 6485 of our era. The solar perigee will then coincide with the vernal equinox; in the former case it coincided with that of autumn.

By reason of the progressive motion of the perigee, the length of the seasons is continually varying. Let AP (figs. 18, 19, 20) represent the line of the apsides, S and W the summer and winter solstices, V and O the vernal and autumnal equinoxes. When the greater axis was perpendicular to the line of the equinoxes, as happened in the year 1250 of our era, the perigee P (fig. 18) coincided

Seasons vary in length.

Fig. 18.

with W the winter solstice; and on that account the time between the autumnal equinox O, and the winter solstice W, was equal to the time between W and V, or between the winter solstice and the vernal equinox. But in this position the equator, which is here represented by VO, divides the ellipse into two unequal portions, the smaller of which must be described in less time than the greater, because the times of description are proportional to the spaces passed over. The summer was therefore, at that time, longer than the winter, and both were divided into equal parts by the solstices. In any other position the seasons differ in length from each other. In the time of Hipparchus, the longitude of the perigee was less than in 1750 by 32°·292, or was 246°·330. The position of the ellipse with regard to the equinoxes was therefore such as is represented in fig. 19, the angle PEW being 270° — 246°·33 = 23° 40′ 12″. The interval between V and S was then 94½ days, and that between S and O only 92½ days. The spring was therefore at that time longer than the summer, and the winter longer than the autumn. The position of the ellipse in 1800 is represented in fig. 20. The angle PEW was then 9° 29′, and the following were nearly the lengths of the seasons:—

Fig. 19.

Fig. 20.

	Days.	Hours.	Min.
from V to S	92	21	45
S to O	93	13	35
O to W	89	16	47
W to V	89	1	42
length of the year, nearly	365	5	49

The spring is therefore at present shorter than the summer, and the autumn longer than the winter.

Eccentricity of the solar orbit.

After describing the position of the transverse axis of the solar ellipse on the plane of the ecliptic, we come next to consider the species of that ellipse, or its eccentricity, on which depend the apparent inequalities of the sun's angular motion. It is evident that this element will be made known if we can by any means determine the ratio of the two segments into which the major axis is divided by the focus. This ratio might seem to be obtainable without any difficulty by comparing the sun's apparent diameters at the perigee and apogee, to which the distances are inversely proportional; but such observations, on account of the irradiation and other difficulties, are liable to considerable uncertainty: it is therefore necessary to have recourse to other methods of estimating the eccentricity, and the variations to which it is subject. These methods are derived from the fundamental law of the elliptic motion, namely, the proportionality of the areas described by the radius vector to the times of description, by which the inequalities of motion and the ellipticity of the orbit are connected with each other; so that when the inequalities are made known by direct observation, the species of the ellipse can be computed from the principles of geometry. It will, however, be necessary to attend more closely than we have yet done to the phenomena resulting from the eccentric position of the earth in the sun's orbit, and to explain some terms technically employed by astronomers to abbreviate and simplify their descriptions.

The sun's motion may be regarded as composed of two distinct parts, namely, a circular uniform motion, which constitutes the principal part of it; and a correction depending on the deviation of the orbit from a circle, which modifies the first, and alternately accelerates and retards the mean angular velocity. To illustrate this, let E (fig. 21) be the earth, PSA the orbit of the sun, AP the line of the apsides, and ♈ ♎ the intersection of the plane of the orbit with that of the equator. While the true sun S moves round his elliptic orbit, describing areas proportional to the times, conceive a fictitious sun *s* to move round the earth in the circumference of a circle of which the radius is equal to EP the sun's distance at the perigee, and with a uniform motion such, that if the two suns set out at the same instant from P, they may also return to the same point together, after having completed each a revolution. At the perigee the radius vector of the real sun is a minimum; his velocity is consequently a maximum, and he therefore advances before the fictitious sun. But his motion relaxes in proportion as his distance from P becomes greater; and at a certain point S of the orbit it becomes equal to that of the fictitious sun, which has then only reached the point *s*. After passing the point S, the angular distance SE*s* continues to diminish on account that the motion of the real sun continues to relax, and it vanishes altogether when he reaches his apogee at A, the fictitious sun arriving at *a* in the same straight line with A and E at the same instant of time. From the apogee to the perigee the phenomena are reversed. The motion of the real sun being then the slowest possible, he at first falls behind the fictitious sun; but his motion continuing to be gradually accelerated, he has again acquired the same velocity when he reaches S′, after which his motion is more rapid than that of the fictitious sun, which he at last overtakes at P. If, therefore, we conceive a radius vector to be drawn from the earth to each of the two suns, those lines will form with each other a variable angle, having its maximum value when the velocities are equal, and vanishing at the perigee and apogee. This angle, namely, SE*s*, is called the *Equation of the Centre*, or *Equation of the Orbit*. It is the correction necessary to be made to the longitude of the sun deduced from his equable motion, in order to have his real longitude. Those quantities which form the difference between the true and mean results are, in astronomy, denominated equations. The ancients employed the term *Prosthaphæresis* in the same sense.

Equation of the centre.

From the perigee to the apogee, the true longitude of the sun is found by adding the equation of the centre to the mean longitude, and in the other half of the orbit by taking the difference of the same quantities. The equation of the centre is a maximum when the sun is at the points S and S′, or when the mean and true motions are equal; and if its value can be obtained from observation at those times, the eccentricity of the orbit may be deduced by means of the geometrical properties of the ellipse. Now the points S and S′ may be found very nearly by observing when the diurnal velocity of the sun is equal to the mean motion, or to 0·985647 parts of a degree. By these observations the angle SES′, which is the difference of the real longitudes of the sun, or of his distances from ♈, will be given. But *s* E *s*′ is also given; for it is the angle which would be described by the sun, in virtue of his mean motion, during the interval between the two observations. Hence the difference between *s*E*s*′ and SES′ is given, being equal to twice SE*s* the maximum equation of the centre, in consequence of the symmetrical position of the points S and S′, and also of *s* and *s*′, in respect of the line of the apsides AP. The accuracy of a result obtained in this manner may appear questionable, on account of the impossibility of determining by observation the exact moment at which the sun's true motion in longitude is equal to his mean motion; but as the real motion varies very little during a few days before and after that epoch, the equation of the centre will be scarcely affected by a slight error in the time. Besides, any error in the result is corrected by taking the mean of a great number of similar observations.

Theoretical Astronomy.

By a comparison of numerous observations of this kind, Delambre found that the greatest equation of the centre, in the year 1776, amounted to 1°·9254, or 1° 55′ 31″·4. In 1801 the same equation was 1° 55′ 27″·3. (See Baily's *Astronomical Tables*, p. 66.)

Having obtained the value of the greatest equation of the centre, the eccentricity of the orbit may be computed from the first two terms of the following series,

$$e = \tfrac{1}{2}\mathrm{E} - \frac{11}{2^8 \cdot 3}\mathrm{E}^3 - \frac{587}{2^{16} \cdot 3 \cdot 5}\mathrm{E}^5 - \&c.$$

in which e represents the eccentricity, and E the greatest equation of the centre. By reversing the series the following expression is found for the greatest equation in terms of the eccentricity, viz.

$$\mathrm{E} = 2e + \frac{11}{2^4 \cdot 3} e^3 + \frac{599}{2^{10} \cdot 5} e^5 + \&c.$$

For an investigation of the above formulæ the reader may consult Biot, *Astronomie Physique*, tom. ii. p. 185.

Secular diminution of the eccentricity of the solar orbit.

It has been discovered by observation, that the equation of the centre of the sun's orbit is subject to a nearly uniform secular diminution. This fact is confirmed by theory, from which also the secular diminution has been assigned. It amounts to 8°·0047 in a century. This phenomenon implies a corresponding diminution of the eccentricity of the solar orbit amounting to ·000037495 in the same time, the semiaxis major being unit. This will be conceived more distinctly by converting the above fraction into some familiar expression of linear magnitude. Supposing the mean distance of the sun to be 96,000,000 of miles, the fraction ·000037495 will represent nearly 3700 miles, so that the annual diminution of the eccentricity is nearly at the rate of 37 miles,—a line which is considerable on the surface of the earth, but which has scarcely an appreciable ratio to the immense distance of the sun. If, however, this diminution, small as it is, were to be continued indefinitely, the eccentricity would ultimately vanish, and the sun's orbit would be changed into a circle; but the theory of universal gravitation proves that, like all the other variations of the elements of the solar system, the variation of the eccentricity is subject to periodic laws. After having continued during a certain time to diminish, the eccentricity will again begin to increase, and will successively pass through all its former values. Thus it will continue to oscillate within certain limits, of which the extent, though not precisely known, cannot be very great: and the solar orbit will eternally preserve its elliptic form, unless the application of some external force shall derange the system of the world, or modify the laws by which it is at present governed.

Determination of the sun's place in his orbit.

Kepler's problem.

The true nature of the solar orbit being known, together with its situation on the plane of the ecliptic, and the amount of its eccentricity, as also the time of a revolution, the sun's longitude may be determined at any assigned epoch. This determination is what is usually termed *Kepler's Problem*, having been first proposed by that great astronomer on the hypothesis of an elliptic orbit. Its solution, which is not susceptible of being exhibited under a finite form, is derived from the principle of the equable description of areas. Let ASP (fig. 22) represent the semi-orbit of the sun, C the centre of the orbit, E the focus occupied by the earth, and let the time and motion be counted from the perigee P. On AP describe a semicircle, on the circumference of which let a point M be supposed to move uniformly, and to describe the semicircle PMA, in the same time in which the sun describes the semi-ellipse PSA. Now, suppose that at the end of a given time t, the sun has moved from P to S; then, denoting by T the time of a complete revolution, and putting π for the semi-circumference, the place of M, at the end of the same time t, will be given by the equation $\mathrm{PM} = \frac{t}{\mathrm{T}} 2\pi$. Through S let a perpendicular be drawn to AP, meeting the semicircle in D and AP in N, and join EM, ES, ED, CM, and CD. The different angles of this figure have received certain technical names, which it is necessary to explain. Then S being the true place of sun, the angle PES is called the *True Anomaly*; PEM is called the *Mean Anomaly*, and PCD is denominated the *Eccentric Anomaly* This last is measured by the arc PMD, which is the perigean distance of a body describing a circle circumscribed about the solar ellipse, and having constantly the same abscis PN as the sun. The word *anomaly* originally signified *inequality*; it now simply designates the angular distance of a planet from its perihelion, seen from the sun, or, as in the present case, the angular distance of the sun from his perigee.

Theoretical Astronomy. Fig. 22.

According to the law of the equable description of areas, we have the sector PCM to PES as the surface of the semicircle to the surface of the semi-ellipse; that is, as the semi-transverse to the semi-conjugate axis, or as ND to NS, according to a well-known property of the ellipse. Hence PCM : PES : : PED : PES, and therefore PCM = PED = PCD — ECD. Now, if we express the arc PM by z, PD by x, the eccentricity EC by e, and make the radius equal to unity, we shall have the sector $\mathrm{PCM} = \frac{1}{2}z$, the sector $\mathrm{PCD} = \frac{1}{2}x$, and the triangle $\mathrm{ECD} = \frac{1}{2}e$. $\mathrm{DN} = \frac{1}{2}e \sin. x$. Substituting, therefore, these expressions in the above equation, it will become, on multiplying both sides of it by 2,

$$z = x - e \sin. x \ldots\ldots\ldots\ldots\ldots\ldots (1.)$$

where z denotes the mean, and x the eccentric, anomaly.

If in this equation x and e were both known, it would be easy to deduce from it the mean anomaly z; but the data are z and e, and the value of x can only be obtained in a series, the equation being a transcendental one. Its resolution gives the value of the eccentric in terms of the mean anomaly; and if another equation can be found in which the eccentric anomaly is expressed in terms of the true, it will only remain to put these two expressions equal to one another in order to have an equation between the mean and true anomaly.

For this purpose it will be necessary to equate two values of the radius vector ES, expressed in terms of the eccentric and true anomalies respectively. Putting $\mathrm{ES} = r$, we shall have, in the first place,

$$r^2 = \mathrm{EN}^2 + \mathrm{NS}^2;$$

but if the semiaxis minor is represented by b, the common equation of the ellipse gives

$$\mathrm{NS}^2 = \frac{b^2}{a^2}(a^2 - \mathrm{CN}^2) = b^2 - \frac{b^2}{a^2}\mathrm{CN}^2;$$

and we have also

$$\begin{aligned}\mathrm{EN}^2 &= \mathrm{EC}^2 + 2\,\mathrm{EC} \,.\, \mathrm{CN} + \mathrm{CN}^2 \\ &= e^2 a^2 + 2ea \,.\, \mathrm{CN} + \mathrm{CN}^2;\end{aligned}$$

therefore, by addition,

$$\mathrm{NS}^2 + \mathrm{EN}^2 = b^2 + e^2 a^2 + 2ea \,.\, \mathrm{CN} + \left(1 - \frac{b^2}{a^2}\right)\mathrm{CN}^2.$$

Now, $b^2 + e^2 a^2 = a^2$, and $1 - \frac{b^2}{a^2} = e^2$; therefore

$$\mathrm{NS}^2 + \mathrm{EN}^2 = r^2 = a^2 + 2ea \,.\, \mathrm{CN} + e^2 \mathrm{CN}^2;$$

consequently

$$r = a + e \,.\, \mathrm{CN}.$$

But $\mathrm{CN} = -a \cos. x$; therefore ultimately

$$r = a(1 - e \cos. x) \ldots\ldots\ldots\ldots\ldots (2.)$$

To obtain a second value of r, let SF be drawn from S to the other focus of the ellipse, and let $SF = r'$. The rectangular triangles ESN, FSN give $SN^2 = r^2 - EN^2$, and $SN^2 = r^2 - (2ea - EN)^2$; therefore $r^2 - EN^2 = r'^2 - (2ea - EN)^2$, whence we derive $r^2 - r'^2 = 4ea \cdot EN - 4e^2a^2$. But by the property of the ellipse $r + r' = 2a$, from which it is easy to deduce $r^2 - r'^2 = 4a^2 - 4ar' = 4ar - 4a^2$; and hence, by equating these two values of $r^2 - r'^2$, $ea \cdot EN - e^2a^2 = ar - a^2$. Now, if we denote the angle PES, which is the true anomaly, by v, then $EN = -r\cos.v$, and consequently by substitution $-ear\cos.v - e^2a^2 = ar - a^2$, whence

$$r = \frac{a(1-e^2)}{1+e\cos.v} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3.)$$

If we now compare the two values of r given by the equations (2) and (3), we shall find

$$\cos.x = \frac{\cos.v + e}{1 + e\cos.v},$$

and therefore, $1 - \cos.x = (1-e)(1-\cos.v)$

$$1 + \cos.x = (1+e)(1+\cos.v);$$

whence, by dividing,

$$\frac{1-\cos.v}{1+\cos.v} = \frac{1+e}{1-e} \cdot \frac{1-\cos.x}{1+\cos.x};$$

consequently, by the trigonometrical formulæ,

$$\tan.\tfrac{1}{2}v = \sqrt{\left(\frac{1+e}{1-e}\right)} \cdot \tan.\tfrac{1}{2}x \quad \ldots\ldots\ldots (4.)$$

The equations (1) and (2) were first given by Kepler, the last is due to Lacaille. The problem of finding the sun's place after any given time is solved analytically by (1) and (4).

To express v the true anomaly, in a series involving the powers of x the mean anomaly, is a problem requiring the aid of the higher analysis, and which it is unnecessary to investigate here. The following are a few of the first terms of the series, in which nt is substituted for x, n being the mean motion in the unit of time, and t the time elapsed since the passage through the perihelion :—

$$v = nt + \left(2e - \tfrac{1}{4}e^3 + \frac{5}{96}e^5\right) \cdot \sin.nt + \left(\frac{5}{4}e^2 - \frac{11}{24}e^4 + \frac{17}{192}e^6\right) \sin.2nt + \left(\frac{13}{12}e^3 - \frac{43}{64}e^5\right) \sin.3nt + \&c.$$

DISTANCE OF THE SUN FROM THE EARTH.

	Semidiameters of the Earth.	English Miles.
In Perigee	23580	93280945
In Apogee	24388	96478967
At Mean Distance	23984	94879956
Greatest diameter of his orbit	47969	189759912

Sun's parallax and distance.

The form of the sun's orbit is discovered from the variations of his apparent diameter in passing from the perigee to the apogee; but in order to obtain a knowledge of its real dimensions, or of the mean distance of the sun from the earth, it is necessary to determine his parallax, that is to say, the angle subtended by the earth's semidiameter as seen from the sun. This angle is too small to be measured directly in the manner which was pointed out when treating of parallax; it is most accurately deduced from observations of the time occupied by an inferior planet in passing over the sun's disk, as will be explained afterwards. From such observations it has been found to be less than 9″, an angle of which the sine is to radius in the ratio of 1 to 23,000 nearly; whence the distance of the sun is about 23,000 times the semidiameter of the earth. The following table exhibits more accurately the numerical results of calculation.

Sun's volume.

When the sun's parallax is known, we are enabled not only to estimate his distance, but also to compare his diameter and magnitude with those of the earth. For example, the mean parallax of the sun is 8″·56; his mean apparent semidiameter, seen from the earth, is 961″·8; the semidiameters of the sun and earth are therefore to each other in the ratio of 961·8 : 8·56, or of 112 to unity nearly. Supposing the sun and earth to be both spherical bodies, which is a supposition sufficiently accurate for the present purpose, their volumes will be to one another as the cubes of their radii; hence the volume of the sun is to that of the earth as the cube of 112 to unity, or the sun's volume is about 1,405,000 times greater than that of the earth.

SECT. III.—*Of the Motion of Translation of the Earth, and the Aberration of Light.*

Hitherto we have regarded the sun as being actually in motion round the earth in an elliptic orbit, of which the earth occupies one of the foci. This supposes the motion which we observe to be real. But we have already seen that all the phenomena of the diurnal revolution of the celestial bodies may be equally well explained by supposing these motions to be only optical illusions, of the same nature as those by which a person sailing rapidly along a river, or the sea-shore, is almost irresistibly led to ascribe the motion to the banks on the shore, even when fully aware that the appearance is only occasioned by his own motion in a contrary direction. In the same manner all the phenomena of the annual motion are susceptible of an equally simple explanation, on the hypothesis that the earth revolves in an elliptic orbit, and that the sun is at rest in one of the foci of the ellipse. In fact, if there were no other bodies in the universe than the earth and the sun, it would be matter of absolute indifference which of the two hypotheses we should adopt in order to explain the appearances. Supposing, for example, the earth to revolve in a circular orbit (the eccentricity, on account of its smallness, being here neglected), and the sun to be placed at the centre; a spectator at E (fig. 23) sees the sun S in the heavens at the point A, and corresponding to the star a on the celestial sphere. If the earth now take the place of the sun, and the sun be placed on the curve at A, the spectator will still see the sun correspond to the star a. Let the earth be transferred from E to E′; the spectator will then see the sun in A′. The sun therefore appears to him to have moved from A to A′, which is exactly the same appearance as would be presented to a spectator at the centre by a real translation of S from A to A′; so that, in respect of the annual motion, the appearances, when referred to the celestial sphere, are precisely the same on either hypothesis. Fig. 23.

If we now consider the phenomena with reference to the earth, we shall find that they may be all equally well explained on the hypothesis of the earth's motion, and the immobility of the sun. The most remarkable phenomenon connected with the annual revolution is the variation of the seasons; and in order to explain their cause, it is only necessary to suppose that the earth, in describing its oblique orbit, always preserves its axis parallel to the same straight line. Let A, B, C, D (fig. 24) repre- Fig. 24.

Theoretical Astronomy.

sent the earth in four different positions of its orbit, *n s* being its axis, and *n* and *s* its north and south poles respectively. While the earth goes round the sun in the order of the letters A, B, C, D, its axis *ns* preserves its obliquity, and always continues parallel to its first direction. At A the north pole inclines towards the sun, and brings all the northern places more into the light than at any other season of the year. But when the earth is at C, the opposite point of the orbit, the north pole declines from the sun, and a less portion of the northern hemisphere enjoys the blessings of his light and heat. At B and D the axis is perpendicular to the plane of the orbit, so that the poles are situated in the boundaries of the illuminated hemisphere, and the sun, being directly over the equator, makes the days and nights equal at all places. These phenomena are illustrated in fig. 25, which represents the situation of the north pole with regard to the limits of illumination, in eight different positions of the orbit. In this figure, Æ is the terrestrial equator, T the tropic of Cancer, the dotted circle the parallel of London, U the arctic or north polar circle, and P the north pole, where all the meridians or hour-circles meet. The spectator is supposed to be placed at the pole of the ecliptic.

Plate LXXVIII. Fig. 25.

When the earth is at the beginning of Libra, about the 20th of March, the sun, as seen from the earth, appears at the beginning of Aries in the opposite part of the heavens, the north pole is just coming into light, and the sun is vertical to the equator, which, with all its parallels, is divided into two equal parts by the circle which forms the boundary between the dark and illuminated hemispheres, and therefore the days and nights are equal all over the earth. As the earth moves in the ecliptic according to the order of the letters A, B, C, D, &c., the north pole P comes more and more into the light, and the days increase in length at all places north of the equator Æ. When the earth comes to the position between B and C, or the beginning of Capricorn, the sun, as seen from the earth, appears at the beginning of Cancer, about the 21st of June; and the north pole of the earth inclines towards the sun, so as to bring into light all the north frigid zone, and more of each of the northern parallels of latitude in proportion as they are farther from the equator. As the earth advances from Capricorn towards Aries, and the sun appears to move from Cancer towards Libra, the north pole recedes from the light, which causes the days to decrease and the nights to increase in length, till the earth comes to the beginning of Aries, and then they are equal as before; the boundary of light and darkness cutting the equator and all its parallels equally. The north pole then goes into the dark, and does not emerge till the earth has completed a semi-revolution of its orbit, or from the 23d of September till the 20th of March. All these phenomena will be readily understood from the bare inspection of the figure; and it will be perceived that what has been said of the northern hemisphere is equally true of the southern in a contrary sense, that is, at opposite seasons of the year.

The only objection against the annual motion of the earth, which at first sight creates some difficulty, is the enormous distance which, on account of the want of annual parallax, that hypothesis makes it necessary to assign to the fixed stars. Abstracting from the precession, which in the region of the poles amounts only to about 20″, the axis of the earth, in every part of its orbit, appears to be directed towards the same point of the starry sphere. It is certain, however, that the radius of the terrestrial orbit is upwards of 90 millions of miles; and therefore, when the earth is at opposite points of this immense circle, its pole ought to be directed to points in the heavens 180 millions of miles distant from each other. Suppose the sun to be at rest in S (fig. 26), the centre of the orbit E*ab*, and the earth to be at the point E. Suppose also A to be the projection of S on the sphere of the fixed stars, and ♈ the first point of the ecliptic. The longitude of A. as seen from E, is the angle A E♈; but when seen from S, the longitude of the same point is A S♈. This last is the *true* longitude of A; A E♈ is the *apparent* longitude, and their difference is the angle S♈E. Now, in the first half of the ecliptic, the apparent longitude will be less than the true, and in the second half greater; hence there ought to result an apparent annual inequality in the sun's longitude. But as such inequality is shown in very few cases, it becomes necessary either to abandon the hypothesis of the earth's motion, or to suppose the distance of the fixed stars to be so great, that, in comparison of it, the radius ES, which exceeds 90 millions of miles. is altogether insensible; and that the whole orbit of the earth, or the ellipse E*ab*, is a mere point in comparison of a great circle of the starry sphere.

Theoretical Astronomy.

Fig 26.

The most convincing proof of the earth's motion is not to be found in any circumstance of which the senses can take immediate cognizance,[1] but is afforded by the full development of the planetary system, and the mutual connection of all the truths of rational astronomy,—by the clearness, simplicity, and coherence which this hypothesis gives to the most complicated phenomena,—and can therefore only be fully appreciated after an attentive study of the whole series of facts which astronomy makes known. There exists, however, one direct proof of the earth's annual motion, in a phenomenon discovered by the accurate observation and patient sagacity of Bradley, although it is one which, we are almost tempted to think, ought to have been perceived *a priori*, after Roemer's discovery of the progressive motion of light. It is known by the name of the *Aberration of Light*, and is manifested in a small difference between the apparent and true places of a star, occasioned by the motion of light combined with that of the earth in its orbit.

Aberration of light.

To illustrate this effect, conceive a body to move in the direction EE′ (fig. 27), and another to impinge on it in the direction SE. To find the direction of the resulting motion, take EC and EA proportional to the two velocities respectively, and, having completed the parallelogram EABC, draw the diagonal EB. The combination of the two motions produces an impression on the eye exactly similar to that which would have been produced if the eye had remained at rest in the point E, and the molecule of light had come to it in the direction ES′; the star, therefore, whose real place is at S, will appear to the spectator at E to be situated at S′. The difference between its true and apparent place, that is, the angle SES′, is the *aberration*, the magnitude of which is obtained from the known ratio of EA to EB, or the velocity of light to that of the earth in its orbit. Now, we know from the phenomena of the eclipses of Jupiter's satellites, that a ray of light describes a line equal to the mean radius of the ecliptic in 8 min. 18 sec. or 498 seconds of time. But the arc described by the earth in that time is found from the proportion

Fig. 27.

$$365^{d}\cdot256 : 498^{s} :: 360^{\circ} : x,$$

whence $x = 20''\cdot45$. It is evident, therefore, that when the directions of the two motions are at right angles, the star S always appears in advance of its real place, in a direction parallel to that of the motion of the earth, by a quantity equal to 20″·45. This quantity, 20″·45, is called the *Constant of Aberration*; but as it has been obtained on the assumption that the earth moves uniformly in a circular orbit, it is evidently not altogether exact, and recourse

[1] It may here be observed that the rotation of the earth *on its axis* has been satisfactorily demonstrated by means of the pendulum, in M. Foucault's celebrated experiment, an account of which will be found under the head PENDULUM.

Theoretical Astronomy

must be had to observation to determine its precise amount. Bradley supposed it to be 20″; Dr Brinkley, from the mean of 2633 comparisons of various stars has deduced the value 20″·37. From a series of observations made by M. Struve the Russian astronomer, the constant of aberration has been determined to be 20″·445, which is probably an exceedingly close approximation, and may be considered as one of the most certain determinations of astronomy. (*Sur le coefficient de l'aberration des étoiles fixes. Petersburg Memoirs*, vol. iii.)

It is easy to see that, on the same principles, there ought also to be a diurnal aberration; but the diurnal rotation of the earth being sixty-five times less rapid than the orbital motion, its effect in producing aberration does not amount to more than 0ˢ·0208, when reduced to seconds of time. It is, however, taken into account in reducing transit observations, and incorporated with the error of collimation.

The magnitude of the angle of deviation SES′ depends on the relative directions of the earth and the visual ray, and may have any value from 0 to 20″·4. Suppose, for example, we observe a star situated in the plane of the ecliptic. When the earth is at that point of its orbit, between the sun and the star, where the tangent to the orbit is perpendicular to the visual ray (which, on account that the star has no sensible parallax, always maintains a parallel direction), the apparent place of the star will be 20″·4 to the eastward of its true place. When the earth is in the opposite point of its orbit the same star will appear to be 20″·4 to the westward of its true place; so that it will appear to have an oscillatory motion on the ecliptic, the range of which is 40″·8, and the period exactly a year. Half-way between these two points the tangent of the orbit is parallel to the direction of the ray of light, and consequently there is no aberration. When the star is not situated in the ecliptic, it will suffer a displacement in latitude as well as in longitude. To render this more intelligible, let EEE (fig. 28) be the ecliptic, E the earth, and A the true place of a star situated at any altitude above the ecliptic. In the direction EA take E*a* to represent the velocity of light, *ab* that of the earth, and in a parallel direction, that is, parallel to the tangent to the ecliptic at E; the line E*b* will now be the apparent visual ray, and the star will seem to be situated at B. Suppose the earth to be placed at different points of its orbit; the lines E*a* will be all parallel to each other on account of the infinite distance of the star A; the lines *ab* will vary little in magnitude, because they are very small in comparison of E*a*, but their directions will undergo every possible change, being always parallel to the tangent at E. At the two points of the orbit where the tangent is parallel to EA, the two lines E*a* and *ab* coincide, and consequently there is no aberration. Let us next suppose the star to be situated in the pole of the ecliptic. In this case the visual ray is constantly perpendicular to the direction of the earth's motion, so that the star will always appear at a distance of 20″·4 from its true place, or appear to describe a small circle about the pole of the ecliptic. In all other situations, out of the ecliptic, the star's apparent path will be an ellipse, the major axis of which, parallel to the plane of the ecliptic, is always 40″·8, while the minor axis varies as the sine of the latitude.

Fig. 28.

The cause of the aberration being known, we have two methods of measuring its quantity, or the extent of the apparent oscillations, viz. by calculating the angle of deviation SAS′ (fig. 27), the tangent of which is to radius as AB to AE, that is, as 1 to 10,313; or, by direct observation, when the star is in opposition to the sun. The two methods give sensibly the same result, and the dimensions of the ellipse described by any star not situated in the ecliptic, in consequence of the aberration, are found to be the same when computed from theory or determined by direct observation. The motion of translation of the earth, therefore, receives a mathematical demonstration from this agreement; and the phenomenon of the aberration, otherwise unimportant on account of its minuteness, thus becomes one of the most interesting discoveries ever made in astronomy. The fact of the earth's orbital motion is, however, rendered so probable by other phenomena, that it must have been universally admitted, although the direct proof had never been discovered.

Fig. 27.

Theoretical Astronomy.

SECT. IV.—*Of the Measure of Time. Equation of Time.*

The notion of time, or of succession, is generally said to be acquired from the aspect of natural phenomena; but from whatever source it may be derived, it is certain that time itself can only be measured by comparing it with something of which the senses can take cognizance. If we have a series of events, such as the oscillations of a pendulum, or the flux and reflux of the sea, uniformly succeeding each other, then time may be measured by the number of such events that have been observed. In like manner, if a body move uniformly in a certain direction, time may be measured by the spaces over which it successively passes. In strict language, motion and time, being heterogeneous quantities, cannot measure one another; but different times are compared with each other by means of the motions that have taken place in those times respectively; for the motions being supposed uniform, equal spaces are passed over in equal times, or, which is the same thing, the times are directly proportional to the spaces described. If, therefore, we assume for unit the time which is absolved while a certain uniform motion takes place, we may obtain, by a simple proportion, the corresponding time of any other similar motion. In this manner we find the ratio of one portion of time to another, although we can form no idea whatever of its absolute quantity.

In order that motion may be employed as a measure of time, it is indispensably requisite that it be perfectly uniform. The only motions having this property, with which we are acquainted, are those of the rotation of the celestial bodies about their own axes. The motion of the sun and planets in their orbits is irregular from various causes: even the successive returns of the fixed stars to the meridian are rendered unequal on account of the precession and nutation; but the diurnal rotation of the earth appears to be affected by no cause of irregularity whatever. Time, therefore, may be properly measured by this uniform motion; and the method of proceeding is as follows. The culmination of a star, or of a given point of the equator, marks the instant at which the day commences, and at any other instant its horary angle determines the portion of the day which has elapsed at the moment of the observation. In order, therefore, to determine the time of an observation, we must find the horary angle formed by the meridian of the observed star with that which passes through the given point where the motion is supposed to begin; in other words, it is necessary to determine the star's right ascension. This, however, when attempted by direct measurement, is a determination attended with difficulty, and liable to considerable uncertainty. Happily the invention of the pendulum has rendered it unnecessary; and astronomers, instead of deducing the time from the right ascensions, determine, on the contrary, the right ascensions by means of the time indicated by the clock. The clock, of which the motion is supposed to be perfectly regular, is adjusted in such a

Theoretical Astronomy.

manner that its index describes 24 hours, while a point of the equator describes an arc of 360°, or makes a complete revolution. This is called a *sidereal day.* The sidereal hour is divided in the usual manner into minutes, seconds, &c.; whence the corresponding arcs are easily found at the rate of 15° to an hour. The point whose culmination marks the origin of time is arbitrary; but astronomers have agreed to choose for that purpose the equinoctial point of Aries, from which the right ascensions are reckoned, so that the hours of the clock and the degrees of the equator may commence at the same instant. This point, it is true, is not, and cannot be, permanently marked by any star; but the right ascension in time of any star whatever being the hour of its transit over the meridian, the star will be in the plane of the meridian at the instant denoted by its right ascension in time. On this account sidereal time expresses the actual right ascension of the zenith; or, as it is frequently termed, *the right ascension of the mid-heaven.*

We have already seen, that on account of the precession of the equinoxes, a star employs somewhat more time than the first point of Aries in returning to the meridian. It is therefore not without some violation of language that the interval between two successive transits of a given point of the equator over the meridian is called a *sidereal* day, which, in its strict acceptation, denotes the time which elapses between two successive transits of the same star; but in this case the difference is so small as to be totally inappreciable. The annual precession in longitude is = 50″·1, and that in right ascension is nearly the same, excepting in regard to the circumpolar stars, which, therefore, are not employed in regulating the clocks. This arc of 50″·1, converted into time, gives 3·3 seconds as the time in which a star will pass the meridian later than the equinoctial point, at the end of the year; and this small quantity being distributed over the whole year, is altogether insensible in short intervals of two or three days. The successive transits of a star, therefore, if we abstract from the nutation and aberration, will mark the sidereal day within the hundredth part of a second of time; and the sidereal year, though not immediately ascertainable by observation, becomes a quantity which may be easily computed. But the regularity of the motion of the stars is deranged by the effects of aberration and nutation; so that in order to measure time with the precision required by modern observers, it is necessary to be acquainted with the minute displacements of the stars. If they seem to return to the meridian after equal portions of absolute time, it is only because our organs are unable to distinguish the hundredths of a second.

The sidereal day is a measure of time which, on account of its uniformity and the facility of observing it, is excellently well adapted for astronomical purposes; but relatively to the ordinary wants of life it is not sufficiently marked;—the culmination of the stars is an event entirely unconnected with civil occupations, and which, for any given star, is even invisible during a great part of the year. The proper motion of the sun causes the sidereal day to commence sometimes by day and sometimes by night, so that great confusion and embarrassment would arise from regulating time and civil affairs by the motions of the stars. On this account the diurnal revolution of the sun has been universally adopted as the measure of time. This is called the *civil day*, and denotes the interval of time which elapses between two successive transits of the sun over the same hour-circle. Most nations have agreed in reckoning it from the inferior semicircle of the meridian, so that the civil day commences and terminates at midnight; but astronomers, in imitation of Hipparchus and Ptolemy, usually reckon the commencement of the day from the instant of the sun's culmination, that is, from noon; and count through the 24 hours from one noon to the following. Thus 9 o'clock in the morning of February 14th is by astronomers called February the 13th at 21 hours. The day thus determined is called the *astronomical* or *solar day;* and being regulated by the true motion of the sun, the time which is measured by it is called *true* or *apparent* time.

Theoretical Astronomy

Astronomical or solar days are not equal. Two causes, in particular, conspire to produce their inequality, namely, the unequal velocity of the sun in his orbit, and the obliquity of the ecliptic. The effect of the first cause is sufficiently sensible. At the summer solstice, when the sun's motion is slowest, the astronomical day approaches nearer the sidereal than at the winter solstice, when his motion is most rapid.

Days vary in length.

To conceive the effect of the second cause, it is necessary to have regard to the motion of the sun in reference to the equator. The sun describes every day a small arc of the ecliptic. Through the extremities of this arc suppose two meridians to pass; the arc of the equator, which they intercept, is the sun's motion for that day referred to the equator, and the time which that arc takes to pass the meridian is equal to the excess of the astronomical day above the sidereal. But it is obvious that at the equinoxes the arc of the equator is smaller than the corresponding arc of the ecliptic, in the proportion of the cosine of the obliquity of the ecliptic to radius: at the solstices, on the contrary, it is greater in the proportion of radius to the cosine of the same obliquity. The astronomical day is diminished in the first case, and lengthened in the second.

To have a mean astronomical day independent of these causes of inequality, astronomers have supposed a second sun to move uniformly on the ecliptic, and to pass over the extremities of the axis of the sun's orbit at the same instant with the real sun. This removes the inequality arising from the inequality of the sun's motion. To remove the inequality arising from the obliquity of the ecliptic, conceive a third sun to pass through the equinoxes at the same instant with the second sun, and to move along the equator in such a manner that the angular distances of the two suns at the vernal equinox shall be always equal. The interval between two consecutive returns of this third sun to the meridian forms the *mean astronomical day. Mean time* is measured by the number of the returns of this third sun to the meridian; and *true time* is measured by the number of returns of the real sun to the meridian. The arc of the equator, intercepted between two meridian circles drawn through the centres of the true sun and the imaginary third sun, when reduced to time, is what is called the *Equation of Time.* This will be rendered plainer by the following diagram.

Mean astronomical day.

Let Z♈z♎ (fig. 29) be the earth; ZFR*z* its axis; *abcde*, &c. the equator; ABCDE, &c. the northern half of the ecliptic from ♈ to ♎, on the side of the globe next the eye; and MNOP, &c. the southern half on the opposite side from ♎ to ♈. Let the points at A, B, C, D, E, F, &c. mark off equal portions of the ecliptic, gone through in equal times by the real sun, and those at *a*, *b*, *c*, *d*, *e*, *f*, &c. equal portions of the equator described in equal times by the fictitious sun; and let Z♈*z* be the meridian.

Fig. 29.

As the real sun moves obliquely in the ecliptic, and the fictitious sun directly in the equator, any point between ♈ and F on the ecliptic must be nearer the meridian Z ♈ *z*, than the corresponding point on the equator from ♈ to *f*, that is to say, than the point whose distance from ♈ is expressed by the same number of degrees; and the

Theoretical Astronomy.

more so, as the obliquity is greater; and therefore the true sun comes sooner to the meridian every day whilst he is in the quadrant ♈F, than the fictitious sun does in the quadrant ♈ *f*; for which reason the solar noon precedes noon by the clock, until the real sun comes to F, and the fictitious to *f*: which two points being equidistant from the meridian, both suns will come to it precisely at noon by the clock.

Whilst the real sun describes the second quadrant of the ecliptic FGHIKL from Cancer to ♎, he comes later to the meridian every day than the fictitious sun moving through the second quadrant of the equator from *f* to ♎; for the points at G, H, I, K, L, being farther from the meridian, their corresponding points at *g*, *h*, *i*, *k*, *l*, must come to it later; and as both suns come at the same moment to the point W, they come to the meridian at the moment of noon by the clock.

In departing from Libra through the third quadrant, the real sun going through MNOPQ towards ♑ at R, and the fictitious sun through *mnopq* towards *r*, the former comes to the meridian every day sooner than the latter, until the real sun comes to R, and the fictitious to *r*, and then they come both to the meridian at the same time.

Lastly, as the real sun moves equably through STUVW, from R towards ♈, and the fictitious sun through *stuvw*, from *r* towards ♈, the former comes later every day to the meridian than the latter, until they both arrive at the point ♈, and then they make it noon at the same time with the clock.

Having explained one cause of the difference between true and mean time, we now proceed to explain the other cause of this difference, namely, the inequality of the sun's apparent motion, which is slowest in summer, when the sun is farthest from the earth, and swiftest in winter, when he is nearest to it.

If the sun's motion were equable in the ecliptic, the whole difference between the equal time as shown by the clock, and the unequal time as shown by the sun, would arise from the obliquity of the ecliptic. But the sun's motion sometimes exceeds a degree in 24 hours, though generally it is less; and when his motion is slowest, any particular meridian will revolve sooner to him than when his motion is quickest; for it will overtake him in less time when he advances a less space than when he moves through a larger.

Now, if there were two suns moving in the plane of the ecliptic, so as to go round it in a year, the one describing an equal arc every 24 hours, and the other describing in the same time sometimes a less arc, and at other times a larger, gaining at one time of the year what it lost at the opposite; it is evident that one of these suns would come sooner or later to the meridian than the other, as it happened to be behind or before the other; and when they were in conjunction, they would both come to the meridian at the same moment.

As the real sun moves unequably in the ecliptic, let us suppose a fictitious sun to move equably in a circle coincident with the plane of the ecliptic. Let ABCD (fig. 30) be the ecliptic or orbit in which the real sun moves, and the dotted circle *abcd* the imaginary orbit of the fictitious sun; each going round in a year according to the order of letters, or from west to east. Let HIKL be the earth turning round its axis in the same direction every 24 hours; and suppose the two suns to start from A and *a*, at the same moment, A and *a* being in the same straight line, and in the plane of the meridian EH. Suppose also that the real sun, when at A, is at his greatest distance from the earth, where his motion is slowest. In the time that the meridian revolves from H to H again, according to the order of the letters HIKL, the real sun has moved from A to F; and the fictitious sun with a quicker motion from *a* to *f*, through a larger arc: therefore the meridian EH will revolve sooner from H to *h* under the real sun at F, than from HE to *k* under the fictitious sun at *f*; and consequently it will then be noon by the sun-dial sooner than by the clock.

Fig. 30.

As the real sun moves from A towards C, the velocity of his motion increases all the way to C, where it is at its maximum. But notwithstanding this, the fictitious sun gains so much upon the real, soon after his departing from A, that the increasing velocity of the real sun does not bring him up with the equally-moving fictitious sun till the former comes to C and the latter to *c*, when each has gone half round its respective orbit; and then being in conjunction, the meridian EH, revolving to EK, comes to both suns at the same time, and therefore it is noon by them both at the same moment.

But the increased velocity of the real sun now being at its maximum, carries him before the fictitious one; and therefore the same meridian will come to the fictitious sun sooner than to the real; for whilst the fictitious sun moves from *c* to *g*, the real sun moves through a greater arc from C to G; consequently the point K has its noon by the clock when it comes to *k*, but not its noon by the sun till it comes to *l*. And although the velocity of the real sun diminishes all the way from C to A, and the fictitious sun by an equable motion is still coming nearer to the real sun, yet they are not in conjunction till the one comes to A and the other to *a*, and then it is noon by them both at the same moment.

Comparison of mean and sidereal time.

Mean solar time and sidereal time being both uniform, it is easy to compare the one with the other, and assign the number of degrees, minutes, &c. which the sun and a star will respectively describe in a given portion of side-real or mean solar time. In a mean solar day the sun's right ascension and mean longitude are increased by 59′ 8″·33; consequently 360° 59′ 8″·33 of the equator pass the meridian in 24 mean solar hours. The sidereal time corresponding to this period is 24 hours 3 min. 56·555 sec.; therefore 24 mean solar hours are equal to 24 hours 3 min. 56·555 sec. of sidereal time; and 24 hours of sidereal time are equal to 23 hours 56 min. 4·0907 sec. of mean solar time, or to 24 hours minus 3 min. 55·9093 sec. This difference of 3 min. 55·9093 sec. is called the *acceleration of the fixed stars* in mean solar time; and the preceding excess of 3 min. 56·555 sec. is the retardation of the sun in sidereal time. Hence the one species of time may be easily converted into the other; and the arc of the equator passed over by the meridian in a given mean time may be calculated. Thus,

$$\frac{360^\circ\ 59'\ 8''.33}{24} = 15^\circ\ 2'\ 27''.84708$$

is the arc described by a star in one hour of mean solar time.

But the process of converting sidereal or mean solar time into true or apparent time, or of computing from the instants of apparent time the corresponding mean solar and sidereal times, is attended with much greater difficulty. The reason is, that the interval between two successive transits of the sun over the meridian, which, in apparent time, measures the day, is a variable quantity; and hence there cannot exist any constant ratio between true and mean time, as there does between mean and sidereal time. The correction or equation by which apparent time is reduced to mean time, is technically called the *Equation of Time*, and is composed of the aggregate of the several variable terms which denote the inequalities of the sun's motion in longitude. Besides the eccentricity,

Theoretical Astronomy.

the obliquity of the ecliptic, and the variations of that obliquity occasioned by the nutation of the earth's axis, it is affected also by the small alterations of the sun's right ascension, which result from the effect of the planetary perturbations on the earth; and hence the equation of time cannot be exactly computed without the aid of Physical Astronomy.

It will be evident, from what has preceded, that the equation of time expresses merely *the difference between the true and mean right ascensions of the sun*, reduced to time. Its different parts may be calculated numerically in the following manner. Let NA (fig. 31) represent the mean motion of the sun during a given interval, then NA is the sun's mean longitude, N being the first point of Aries. Let NA = M, and from this mean longitude subtract the longitude of the apogee, the remainder will be the sun's mean anomaly. From the mean anomaly let the equation of the centre be found and denoted by E. Take AB = E, then NB = M + E is the longitude corrected for the eccentricity.

Fig. 31.

Let us next suppose BC to be the small quantity by which the sun's longitude is increased in consequence of the perturbations of the planets, and let BC = P; then NC = M + E + P is the true and exact longitude of the sun. Through C let the arc CD be drawn perpendicular to the equator; the point D will be that point of the equator which passes the meridian at the same time with the sun. Let R = NC — ND = the reduction to the ecliptic; we have then the sun's right ascension = M + E + P — R.

Let NF = NA, and F will be the place which the sun would occupy in the equator at the same instant that he occupies the point A in the ecliptic, if he moved uniformly in the former circle; for NF as well as NA will represent the mean diurnal motion of 59′ 8″·33 multiplied by the number of days elapsed in the interval between the equinox N and the time of the observation. The mean sun would therefore pass the meridian with the point F, whereas the true sun passes it with the point D; therefore, at the instant of true noon, when the sun C and the corresponding point D are on the meridian, the mean sun is at a distance from D expressed by the arc FD = M + E + P — R — M = E + P — R. Now, the arc of the equator FD measures the horary angle between the mean and the true sun, or the angle at the pole between the meridian and the hour-circle passing through D; it is therefore converted into time by the following proportion:—

360° : FD :: 24 mean solar hours : time from true noon; consequently the difference between mean and true noon, or the equation of time,

$$= \frac{\text{FD} \times 24^h}{360^\circ} = \tfrac{1}{15}(\text{E} + \text{P} - \text{R}) = d\text{T}.$$

But this equation is not yet perfectly accurate: it requires to be corrected for the effects of nutation. Now it is known that the variation of the mean longitude of the sun, arising from the unequal precession of the equinoxes in consequence of the nutation occasioned by the inclination of the lunar orbit, is expressed by the formula 18″ sin. (360° — moon's node) = 18″ sin. N. This variation, reduced to the direction of the equator, will therefore be 18″ sin. N cos. *e* (*e* being the obliquity of the ecliptic). The difference between the two expressions is 18″ sin. N (1 — cos. *e*) = 36″ sin.^{2} $\frac{1}{2}e$ sin. N = 1″·4887 sin. N, which, reduced to time, becomes 0·09925 sec. × sin. N. This small correction, amounting to less than a tenth of a second, was long omitted in computing the equation of time. When it is included, that equation becomes

$$d\text{T} = \tfrac{1}{60}(\text{E} + \text{P} - \text{R}) + 0{\cdot}09925 \text{ sec.} \times \text{sin. N}.$$

Theoretical Astronomy.

The quantities E, P, R, and N, are to be computed separately from the astronomical tables; and it must be observed, that the result will be expressed in *mean solar time*.

The cosine of the obliquity, that is, cos. 23° 28′, is equal to ·9173 = $\frac{11}{12}$ very nearly. Hence, since the equation of time is equal to the sun's true right ascension, diminished by his mean longitude and the effects of nutation in right ascension (= ND — NA $\mp$ 18″ sin. N cos. *e*), it may, on denoting the true right ascension by A, be expressed as follows:—

$$d\text{T} = \text{A} - \text{M} \mp 18'' \text{ sin. N} \times \tfrac{11}{12}.$$

This is the form under which the equation of time was expressed by Dr Maskelyne.

The equation of time is at its maximum about the 3d of November, when it amounts to 16′ 16″·7, and is subtractive. At four different times of the year it vanishes, namely, about the 25th of December, the 16th of April, the 16th of June, and the 1st of September. These epochs, however, do not remain constant; for, on account of the change which the line of the apsides is constantly undergoing in reference to the line of the equinoxes, the difference between the true and mean right ascensions of the sun—in other words, the equation of time—varies continually in different years.

Sect. V.—*Of the Spots of the Sun, his Rotation, and Constitution.*

The sun, the great source of light, heat, and animation, when beheld with the naked eye, appears only as a luminous mass of uniform splendour and brightness; but when examined with the telescope, his surface is frequently observed to be mottled over with a number of dark spots, of irregular and ill-defined forms, and constantly varying in appearance, situation, and magnitude. These spots are occasionally of immense size, so as to be even visible without the aid of the telescope; and their number is frequently so great that they occupy a considerable portion of the sun's surface. Dr Herschel observed one in 1779, the diameter of which exceeded 50,000 miles, more than six times the diameter of the earth; and Scheiner affirms that he has seen no less than 50 on the sun's disk at once. Most of them have a deep black nucleus, surrounded by a fainter shade, or *umbra*, of which the inner part, nearest to the nucleus, is brighter than the exterior portion. The boundary between the nucleus and umbra is in general tolerably well defined; and beyond the umbra a stripe of light appears more vivid than the rest of the sun.

The discovery of the sun's spots has been attributed to different astronomers. They appear to have been first taken notice of in a work of Fabricius, the friend of Kepler, which was published at Wittenberg in 1611, under the title of *Joh. Fabricii Phrysii de Maculis in Sole Observatis, et Apparente earum cum Sole Conversione Narratio.* It contains, however, nothing more than a few vague conjectures respecting the spots, the phenomena of which he could not have observed with any degree of accuracy, inasmuch as he seems to have been unacquainted with any method of protecting the eye by intercepting a portion of the solar rays; for he recommends to those who should repeat his observations, to admit into the telescope only a small portion of the sun at once, till the eye should by degrees become able to support the full blaze of light. About the same time the discovery was warmly disputed by the illustrious Galileo, and Scheiner, a German Jesuit, professor of mathematics at Ingolstadt. The whole circumstances connected with this dispute are narrated at great length by Galileo in his work entitled *Istoria e Di-*

Theoretical Astronomy

mostrazioni intorno alle Macchie Solari, e loro Accidenti, from which it appears certain that he observed the spots so early as April 1611. In a letter published by him in 1612, he remarks that the spots are situated on the surface of the sun, or that at least their distance from it is imperceptible; that the time of their continuance varies from 2 or 3 to 30 or 40 days; that their figures are irregular and variable; that some are seen to separate, and others to unite, even on the middle of the disk; that besides these peculiar motions, they have also a common motion, in virtue of which they traverse the disk in parallel lines. From this general motion he infers that the sun turns on an axis from west to east; and he adds as a curious remark, that the spots are confined within a zone extending only about 28 or 29 degrees to the north and south of the sun's equator. Galileo illustrates all these positions by mathematical reasoning, and by drawings of the spots made on many successive days.

Scheiner's observations were first announced in January 1612, in three letters addressed to his friend Marc Velser, a magistrate of Augsburg. In the first of these, the date of which is November 1611, he says that he had observed the spots seven months before, but that, having a different object in view, he had given little attention to them. He observed them again in the following October, and at that time imagined the appearance was owing to some imperfection of his telescope, till he was convinced by repeated observations that it was necessary to refer it to the sun. From these remarks it is pretty clear that Scheiner had formed no accurate notions respecting the spots before October 1611, that is, six months after they had been observed by Galileo. Scheiner made the observation of the solar spots his whole occupation during the following eighteen years, in the course of which he discovered the position of the solar equator, and formed a theory much more complete than that of Galileo. The account of his observations was published in 1630, under the title of *Rosa Ursina, sive Sol ex admirando Facularum et Maculorum suarum Phænomeno Varius*, &c.

The discovery of the solar spots has also been claimed for our countryman Harriot. Amidst these conflicting pretensions it is perhaps impossible to arrive at the truth; but the matter is of little importance; the discovery is one which followed inevitably that of the telescope, and an accidental priority of observation can hardly be considered as establishing any claim to merit.

The solar spots furnish an extensive subject of curious speculation, but in an astronomical point of view they are chiefly interesting on account of their establishing the fact, and affording the means of determining the period, of the rotation of the sun. In order to obtain a precise idea of the position of a spot, and the path which it describes, it is necessary to project that path on the plane passing through the centre of the sun, and perpendicular to the visual ray drawn from the earth to the sun's centre.

Fig. 32. Suppose the diameter of a circle ASB (fig. 32) to be divided into as many parts of unity as there are seconds in the apparent diameter of the sun. Let CP be taken equal to the number of seconds contained in the difference of the longitudes of the spot and the sun's centre, and the perpendicular PM equal to the number of seconds in the latitude of the spot; then M will represent its position on the surface of the sun. By repeating the same operation a number of days consecutively, a series of points M M′ M″, &c. will be obtained in the apparent path of the spot on the sun's disk, or rather in the projection of that path on the plane perpendicular to the visual ray. This projection is in general an oval slightly differing from an ellipse; and it is found that all the spots observed at the same time describe similar and parallel curves. They also return to the same relative positions in the same time, and their period is about 27⅓ days. Theoretical Astronomy.

The paths described by the spots undergo very considerable changes, according to the season of the year at which they are observed. About the end of November and beginning of December they appear simply as straight lines M*m*, M′*m*′, M″*m*″ (fig. 33), along which the spots move in the direction M*m*, that is, they enter on the eastern and disappear on the western edge of the sun's disk; and the points at which they disappear are more elevated, or nearer the north pole of the ecliptic, than those at which they enter. After a certain time the lines M*m* begin to assume a curved appearance, and form ovals, as represented in fig. 34. During the winter and spring the convexity of the ovals is turned towards the north pole of the ecliptic; but their inclination, or rather the inclination of the straight lines joining their extreme points, to the plane of the ecliptic continues to diminish, and about the beginning of March disappears; so that the points at which they seem to enter and leave the sun's disk are equally elevated, as in fig. 35. From this time the curvature of the ovals diminishes; they become narrower and narrower till about the end of May or beginning of June, when they again appear under the form of straight lines (fig. 36); but their inclinations to the ecliptic are now precisely in a contrary direction to what they were six months before. After this they begin again to expand, as in fig. 37, and their convexity is now turned towards the south pole. Their inclinations also vary at the same time, and about the commencement of September they are seen as represented in fig. 38; the points at which they enter and disappear being again equally elevated. After this period the ovals begin to contract and become inclined to the ecliptic, and by the beginning of December they have exactly the same direction and inclination as they had the previous year. Fig. 33. Fig. 34. Fig. 35. Fig. 36. Plate LXXIX. Fig. 37. Fig. 38.

These phenomena are renewed every year in the same order, and the same phases are always exhibited at corresponding seasons. Hence it is evident that they depend on a uniform and regular cause, which is common to all of them, since the orbits described by the various spots are exactly parallel, and subject in all respects to the same variations. The simplest method of explaining the phenomena is to suppose with Galileo that the spots are adherent to the surface of the sun, and that the sun uniformly revolves round an axis inclined to the axis of the ecliptic. If the axis of revolution were perpendicular to the plane of the ecliptic, the spots, supposing them to adhere to the sun's surface, would describe circles parallel to that plane, which, seen from the earth, would appear as so many parallel straight lines; but by supposing the axis to have a suitable inclination, all the phenomena become explicable in a very simple manner. While the sun is carried round in his orbit, his axis, constantly preserving its parallelism, will successively assume different positions relatively to the earth; and the planes of the circles described by the spots, which planes are always perpendicular to the axis, will consequently be presented to us under different inclinations; hence the variations of their apparent curvature. In two opposite points of the orbit the visual ray drawn from the earth to the centre of the sun is perpendicular to the axis of rotation. In these two positions the poles of the sun, or the points in which the axis meets the surface, are both visible at the same moment, and the spots appear to move in parallel straight lines. But as the axis retains this perpendicular position only for an instant, and declines from it very sensibly while the spot traverses the sun's disk, the path of

Theoretical Astronomy.

the spots over the entire disk is neither a straight line nor an ellipse, one of which it would necessarily be if the sun, while revolving about his axis, did not change his place in his orbit. When the axis is not perpendicular to the visual ray, the path of the spots will appear to be a curve of which the concavity is turned towards that pole which is visible from the earth. This inclination of the solar axis to the plane of the ecliptic also explains the reason why the points of the disk at which the spots appear are more elevated during one half of the year, and more depressed during the other half, than those at which they disappear. It will also follow from the same hypothesis, that the curvature of the ovals must be the greatest possible when the straight lines joining their extremities are parallel to the ecliptic; and, on the contrary, least when the same straight lines are most inclined to the ecliptic; all which is exactly conformable to observation.

The various appearances which we have now described may be accurately represented by means of a common celestial or terrestrial globe. Let the wooden horizon of the globe, which is here supposed to represent the sun, be placed horizontally in the same plane with the eye of the spectator, and the pole be inclined about 7° from the zenith. The wooden horizon will now represent the ecliptic; and if the spectator walk round the globe, always keeping his eye in the plane of the wooden horizon, the circles of latitude will appear to him as ellipses of different inclinations and eccentricities: in two opposite points they will appear as straight lines, and, in short, exhibit in their various positions all the phenomena of the oval paths described by the spots of the sun.

The consequences deduced from the hypothesis of the rotatory motion of the sun are so perfectly conformable with observation, as to render the inference inevitable, that *the sun revolves from west to east, on an axis inclined about* 93° *to the plane of the ecliptic.* The plane which passes through the centre of the sun, perpendicular to the axis of rotation, is the *Equator* of the sun; the straight line joining the points in which it intersects the ecliptic is called the *Line of the Nodes* of the equator. The *Nodes* themselves are the two opposite points in which this straight line, produced indefinitely, meets the celestial sphere.

In order to determine the situation of the solar axis in space, it is necessary to find its inclination to the ecliptic, and the angle which the line of the nodes makes with any given line on the plane of the ecliptic, for example, with the line of the equinoxes. The requisite data for the solution of this problem are three different positions of the same spot, which must be obtained by observation.

Fig. 39. Let S (fig. 39) be the centre of the sun's disk, AB a parallel to the terrestrial equator, and M the place of a spot, the co-ordinates of which, as referred to AB, are SX and MX. In this figure the earth is supposed to be situated in a straight line passing through S perpendicular to the plane of the paper, and it is to be recollected that SX and MX are in fact arcs of the solar globe, though so small when seen from the earth that they may be regarded as straight lines. By comparing the times of the transits of B, the border of the disk, and the spot M, we shall find BX, from which, as SB the semidiameter of the sun is known, we shall have SX the difference of the right ascensions of the spot and sun's centre. The line CY, which is the difference of the declination of the border of the disk and that of the spot, is measured by the micrometer. This will give MX the declination of the spot.

Now, tan. $MSX = \frac{MX}{SX}$, and $SM = \frac{SX}{\cos. MSX}$; therefore SM is also a known quantity. Let EE be the ecliptic, e = obliquity of the ecliptic, and $\odot$ = the longitude of the sun. The angle BSE, which is technically called the *Angle of Position*, is the complement of the angle made by the ecliptic with the circle of declination passing through the sun, and is therefore given by the formula tan. BSE = tan. e cos. $\odot$: hence MSE (=MSX—BSE) is also given. On SE let fall the perpendicular Mm, then Mm = SM sin. MSE is the geocentric latitude of the spot, and Sm = SM cos. MSE is the difference between its geocentric longitude and that of the centre of the sun: the object is now to determine the angles subtended by these lines at the centre of the sun, that is, to convert the *geocentric* into *heliocentric* latitudes and longitudes.

Theoretical Astronomy

Suppose two straight lines to be drawn from the earth, one to the centre of the sun, and the other to the centre of the spot M, and let θ be their inclination, which is measured by SM, and is consequently known, being the geocentric distance of the spot from S, the centre of the sun's disk. Let R = distance of the sun's centre from the earth, r = semidiameter of the sun, φ = the angle made at the centre of the sun by the straight lines drawn from it to the earth and the spot M, and let ψ be the remaining angle of the triangle formed by the lines joining the earth, the centre of the sun, and the spot. We have then r : R : : sin. θ : sin. ψ, whence sin. $\psi = \frac{R}{r}$ sin. θ. But R : r as radius to the sine of half the sun's true diameter; therefore sin. $\psi = \frac{\text{sin. } \theta}{\text{sin. } \frac{1}{2} \text{ sun's diameter}}$.

Now $\varphi = 180° - \psi - \theta$, consequently we have the number of degrees, minutes, and seconds in φ, the heliocentric distance of the spot from the straight line which joins the centres of the earth and sun. Having thus obtained the hypothenuse SM in parts of a great circle of the solar orb, the sides Sm and Mm will be obtained in similar parts from the common trigonometrical formulæ for the resolution of a right-angled spherial triangle. These formulæ give

tan. Sm = tan. SM cos. MSE,
sin. Mm = sin. SM sin. MSE.

It will be remarked that Mm is the heliocentric latitude of the spot, Sm the difference of its longitude and that of the earth; and as the longitude of the earth is equal to 180° + that of the sun, the heliocentric longitude of the spot will be 180° + $\odot$ — Sm if the spot is behind or to the east of the centre of the sun, and 180° + $\odot$ + Sm if it precedes the centre.

Position of solar axis.

In this manner the heliocentric longitudes and latitudes of the spots are deduced from their observed right ascensions and declinations. The next step is to show how they are employed in determining the position of the solar axis. This problem is in practice somewhat laborious, although the principles on which its solution rests are sufficiently simple. The planes of the circles described by the spots are parallel to the sun's equator: if, therefore, the position of one of them can be found, the position of the equator, and consequently of the axis, will be found at the same time. Now, the position of a plane is determined by three given points through which it is required to pass; consequently, by three observations of the same spot, we shall have three points in its plane, and thence the plane itself. The problem is therefore one of pure geometry, and may be solved in various ways. The results of the most accurate observations make the inclination of the solar equator to the ecliptic amount to 7° 19′ 23″ or, 7°$\frac{1}{3}$ very nearly; and the heliocentric longitude of the ascending node, that is, the point in which the equator of the sun intersects the ecliptic, in passing from

south to north, 80° 7′ 4″. The position of the node seems to undergo no variation, except such as may be supposed to arise from the precession of the equinoxes.

It has already been mentioned that the mean time in which a solar spot returns to the same position, relatively to the earth, is 27·3 days. This, however, is not the time in which the sun makes a revolution about his axis. In the interval of 27·3 days the sun describes in the ecliptic an arc equal to 26°·91 (for 365ᵈ·25 : 27ᵈ·3 :: 360° : 26°·91), and by virtue of this motion alone he exhibits every day different points of his surface, the whole of which would be successively shown to the earth in the course of a year, independently of the motion of rotation. Hence results an apparent annual rotation round an axis perpendicular to the ecliptic, and we must abstract the effects of this optical illusion in order to arrive at the time of a real rotation. This apparent rotatory motion will be easily understood by referring to fig. 40, in which S is the sun, E the earth, and C the point in which the visual ray ES intersects the surface of the sun. Suppose the sun to have advanced in his orbit from S to S′, the visual ray drawn from the sun's centre to the earth will now meet the surface in a different point C′, and the angular distance between C and C′ will be found by drawing S′E′ parallel to SE; for the point *c* in which S′E′ meets the surface will correspond to C, and the arc C′*c*, or the angle E′S′E, will be the apparent rotation, while the sun advances in his orbit from S to S′. Now, the angle E′S′E is equal to S′ES, or the apparent rotatory motion is equal to the angular motion of the sun in his orbit; hence, since the real rotation is in a contrary direction, it is obvious that, if the axis were perpendicular to the plane of the ecliptic, when a spot appears to have made one revolution, it has in reality passed over an arc equal to 360° + 26°·91, or 386·91 degrees. By a simple proportion, therefore,

Fig. 40.

386·91 : 360 : : 27·3 : 25·4;

and consequently 25·4 days is the real time of the sun's revolution. This result is, however, not quite accurate, on account of its having been supposed that the axis of rotation is perpendicular to the ecliptic, whereas it differs from a perpendicular to that plane by 7°⅓; but the correction necessary on account of the difference is so small as to fall far within the limits of the errors to which the observations are liable; it is therefore unnecessary to have regard to it.

Observations liable to uncertainty.

Observations of the spots, from which the elements of the sun's rotation are deduced, are attended with a very considerable degree of uncertainty. The semidiameter of the sun, which at the surface of the earth subtends an angle of only 16′, or 960″, is equivalent to 90° at the centre of the sun. Hence the error of a single second (and it is impossible to answer for one or two seconds in observations of this sort) corresponds to about 338″, or 5′ 38″, on the surface of the solar globe. An observer may, therefore, notwithstanding the greatest care, be mistaken to the extent of 10′ with regard to the length of a heliocentric arc; and when to this we add, that the margins of the spots are ill defined, and even changeable, so that their centres, which it becomes necessary to observe, are not always the same, it will not appear surprising that a considerable discordance exists among the results of different observations. The uncertainty respecting the time of rotation amounts to no less than 10 or 12 hours. From a careful discussion of a numerous set of observations, Delambre found the time of rotation to be only 25·01154 days, instead of 25·4 given above, and he remarks that, in order to render the last-mentioned number admissible, it is necessary to suppose either an error of 2° 22′, which is scarcely possible, or else that the spot has a proper motion in the same direction as the motion of rotation of the earth and all the planets.

From four different combinations of equations, derived from eleven observations of the same spot, Delambre computed the following table of the elements of rotation.

	Node.	Inclination.	Revolution.	Synodic Revol.
1	80° 45′ 7″	7° 19′ 17″	25ᵈ 0ʰ 17ᵐ	26ᵈ 4ʰ 17ᵐ
2	79 21 35	7 12 37		
3	80 33 40	7 16 33		
4	79 47 55	7 29 4		
	80 7 4	7 19 23	Diurnal motion 14°·394	

With regard to observations on the sun's spots, Delambre remarks that he attaches little value to them, first, because it is impossible to make them well; and, secondly, because, even if they were sure, they only lead to results of little importance to astronomy. He discussed a hundred different spots, each observed at least three times by Messier, and deduced thirty different determinations of the elements of rotation. The more he multiplied his calculations, the more certain he became of the impossibility of a good solution; of which, indeed, there is no other chance than in a compensation of errors, little probable on account of their enormous magnitudes. These discrepancies render it probable that the spots, besides partaking of the general motion of the solar globe, have also proper motions either of displacement, or occasioned by a change of form, which may long prevent this part of astronomy from reaching a greater degree of exactness than it has already attained.

From the circumstance that the sun is incontestably endowed with a rotatory motion, Lalande concluded that, according to the rules of probability, he ought also to have a motion of translation in space. This idea was adopted by Herschel, and has since been sufficiently proved. It explains some, though not all, of the proper motions which have been supposed to be observed among the stars. If, indeed, the stars are so many suns, revolving like ours each on its own axis of rotation, it is extremely probable that they have also motions of translation; and thus, there being no fixed points in the heavens, the problem of their proper motions becomes so complicated as to be altogether insoluble.

The only interesting fact which has been deduced from the observations of the solar spots is the rotation of the sun. The curious appearances which they exhibit have, however, attracted great attention, and given rise to numerous theories respecting the constitution of that immense body which governs and vivifies the planetary system. We will now proceed to give a brief account of the appearances, and mention some of the theories that have been founded on them; premising, that after all that has been written on this subject, we are not yet, and probably never will be, in possession of any definite knowledge. The nature of the spots, and the physical constitution of the sun, afford fruitful subjects of harmless conjecture and speculation, but form no part of science.

Appearances of the spots.

The phenomena of the solar spots, as delivered by Scheiner and Hevelius, may be summed up in the following particulars. 1. Every spot which has a nucleus, or comparatively dark part, has also an umbra, or fainter shade surrounding it. 2. The boundary between the nucleus and umbra is always distinct and well defined. 3. The increase of a spot is gradual, the breadth of the nucleus and umbra dilating at the same time. 4. In like manner the decrease of a spot is gradual, the breadth of the nucleus and umbra contracting at the same time.

Theoretical Astronomy

5. The exterior boundary of the umbra never consists of sharp angles, but is always curvilinear, how irregular soever the outline of the nucleus may be. 6. The nucleus of a spot, whilst on the decrease, often changes its figure by the umbra encroaching irregularly upon it, insomuch that in a small space of time new encroachments are discernible, whereby the boundary between the nucleus and umbra is perpetually varying. 7. It often happens, by these encroachments, that the nucleus of a spot is divided into two or more nuclei. 8. The nuclei of the spots vanish sooner than the umbra. 9. Small umbræ are often seen without nuclei. 10. An umbra of any considerable size is seldom seen without a nucleus in the middle of it. 11. When a spot which consisted of a nucleus and umbra is about to disappear, if it is not succeeded by a *facula* or spot brighter than the rest of the disk, the place where it was is soon after not distinguishable from the rest.

In the *Philosophical Transactions*, vol. lxiv. Dr Wilson, late professor of astronomy at Glasgow, has given a dissertation on the nature of the solar spots, in which he mentions the following appearances. 1. When the spot is about to disappear on the western edge of the sun's limb, the eastern part of the umbra first contracts, then vanishes, the nucleus and western part of the umbra remaining; then the nucleus gradually contracts and vanishes, while the western part only of the umbra remains. At last this disappears also; and if the spot remains long enough to become again visible, the eastern part of the umbra first becomes visible, then the nucleus; and when the spot approaches the middle of the disk, the nucleus appears environed by the umbra on all sides, as already mentioned. 2. When two spots lie very near to one another, the umbra is deficient on that side which lies next to the other spot: and this will be the case, though a large spot should be contiguous to one much smaller; the umbra of the large spot will be totally wanting on that side next the small one. If there are little spots on each side of the large one, the umbra does not totally vanish, but appears flattened or pressed in towards the nucleus on each side. When the little spots disappear, the umbra of the large one extends itself as usual. This circumstance, he observes, may sometimes prevent the disappearance of the umbra in the manner above mentioned; so that the western umbra may disappear before the nucleus, if a small spot happens to break out on that side.

In the same volume, p. 337, the Rev. Dr Wollaston observes that the appearances mentioned by Dr Wilson are not uniform. He positively affirms that the faculæ or bright spots on the sun are often converted into dark ones. "I have many times," says he, "observed near the eastern limb a bright facula just come on, which has the next day shown itself as a spot, though I do not recollect to have seen such a facula near the western one after a spot's disappearance. Yet, I believe, both these circumstances have been observed by others, and perhaps not only near the limbs. The circumstance of the faculæ being converted into spots, I think I may be sure of. That there is generally, perhaps always, a mottled appearance over the face of the sun, when carefully attended to, I think I may be as certain. It is most visible towards the limbs, but I have undoubtedly seen it in the centre; yet I do not recollect to have observed this appearance, or indeed any spots, towards the poles. Once I saw, with a twelve-inch reflector, a spot burst to pieces while I was looking at it. I could not expect such an event, and therefore cannot be certain of the exact particulars; but the appearance, as it struck me at the time, was like that of a piece of ice when dashed on a frozen pond, which breaks to pieces and slides in various directions." He also observes, that the nuclei of the spots are not always in the middle of the umbræ, and gives the figure of one seen on the 13th of November 1773, which is a remarkable instance to the contrary. Theoretical Astronomy

The faculæ, or bright spots, were observed with particular attention by Messier, who frequently saw them enter on the eastern limb of the sun, disappear as they approached the centre of the disk, re-appear on the opposite limb, and continue visible, as they had done at the time of their first appearance, for about three days, till they were carried off the disk by the rotation of the sun. Spots frequently broke out in these faculæ, and when this did not happen, they were succeeded by spots which generally became visible on the following day; and from the regularity of this occurrence, he was enabled to predict the appearance of a spot 24 hours before it entered on the sun's disk. He observed, also, that the magnitude of the spots was proportional to the brightness of the antecedent faculæ. Like the spots, the faculæ are generally confined to the equatorial regions of the sun; but they have been occasionally observed by Schroeter on every part of the disk.

Theories regarding the spots.

To explain these singular appearances, numerous theories, more or less plausible, have been proposed, but all resting on many gratuitous assumptions, and subject to great difficulties. Scheiner imagined that the spots do not belong to the sun, but supposed them to be inferior planets revolving at no great distance from the central luminary. Galileo, Hevelius, and others, have supposed them to be scoriæ floating in the inflammable liquid matter of which they imagined the sun to be composed. This opinion, although it accounts for the appearance of the spots in the equatorial regions of the sun, to which such scoriæ would be carried by the centrifugal force resulting from his rotation, cannot be reconciled with the regularity with which the spots frequently re-appear on the eastern limb of the sun. Dr Wilson, having observed that the spots situated near the edge of the disk are narrow, and without a penumbra on the side next the centre, and that only the central spots are completely surrounded by a penumbra (appearances which would be exactly represented by a conical gulf or cavity presented to us under different aspects by the revolution of the sun), was led to adopt the opinion, that the appearances of the spots are occasioned by real excavations in the solar globe. He supposed the sun to consist of a dark nucleus, covered only to a certain depth by a luminous matter, not fluid, through which openings are occasionally made by volcanic or other energies, permitting the solid nucleus of the sun to be seen; and that the umbra which surrounds the spot is occasioned by a partial admission of the light upon the shelving sides of the precipice opposite to the observer. It is evident that, in proportion as these excavations are seen obliquely, their apparent dimensions will be diminished; one of the edges will disappear as it approaches the sun's limb, or come more into view as it advances towards the middle of the disk; when the spot is about to leave the disk, the bottom of the excavation, or the nucleus seen through it, will first disappear, but a sort of faint or obscure spot will remain visible as long as the visual ray penetrates the cavity. These appearances are all conformable to the laws of perspective; but Dr Wilson, wishing to give a still more palpable demonstration of the accuracy of his theory, fitted up a large globe, into which holes of the proper dimensions were inserted; and this machine being placed at a distance, and made to revolve, was found, when examined through a telescope, to exhibit in the course of its revolution all the phenomena of the solar spots.

Theoretical Astronomy.

Dr Wilson's theory was keenly combated by Lalande, who adduced several observations of his own, and some by Cassini, that could not be explained by means of it; and urged with reason, that an hypothesis, founded on the uniformity of appearances which in reality are exceedingly variable, was entitled to little consideration. Lalande himself supposed the spots to be scoriæ which have settled or fixed themselves on the summits of the solar mountains; an opinion which he grounded on this circumstance, that some large spots which had disappeared for several years were observed to form themselves again at the identical points at which they had vanished.

Herschel's observations

The late Sir William Herschel, with a view to ascertain more accurately the nature of the sun, made frequent observations upon it from the year 1779 to the year 1794. He imagined the dark spots on the sun to be mountains, which, considering the great attraction exerted by the sun upon bodies placed at its surface, and the slow revolution it has upon its axis, he thought might be more than 300 miles high, and yet stand very firmly. He says that in August 1792 he examined the sun with several powers from 90 to 500, when it evidently appeared that the dark spots are the opaque ground or body of the sun, and that the luminous part is an atmosphere, through which, when interrupted or broken, we obtain a view of the sun itself. Hence he concluded that the sun has a very extensive atmosphere, consisting of elastic fluids that are more or less lucid and transparent, and of which the lucid ones furnish us with light. This atmosphere, he thought, cannot be less than 1843, nor more than 2765 miles in height; and he supposed that the density of the luminous solar clouds needs not be much more than that of our aurora borealis, in order to produce the effects with which we are acquainted. The sun, then, if this hypothesis be admitted, is similar to the other globes of the solar system with regard to its solidity, its atmosphere, its surface diversified with mountains and valleys, its rotation on its axis, and the fall of heavy bodies on its surface; it therefore appears to be a very eminent, large, and lucid planet, the primary one in our system, disseminating its light and heat to all the bodies with which it is connected.

Herschel supposed that there are two regions or strata of solar clouds; that the inferior stratum is opaque, and probably not unlike our own atmosphere, while the superior is the repository of light, which it darts forth in vast quantities in all directions. The inferior clouds act as a curtain to screen the body of the sun from the intense brilliancy and heat of the superior regions, and, by reflecting back nearly one half of the rays which they receive from the luminous clouds, contribute also greatly to increase the quantity of light which the latter send forth into space, and thereby perform an important function in the economy of the solar system. The luminous clouds prevent us in general from seeing the solid nucleus of the sun; but in order to account for the spots, he supposes an empyreal elastic gas to be constantly forming at the surface, which, carried upwards by reason of its inferior density, forces its way through the planetary or lower clouds, and mixing itself with the gases which have their residence in the superior stratum, causes decompositions of the luminous matter, and gives rise to those appearances which he describes under the name of *corrugations*. Through the openings made by this accidental removal of the luminous clouds, the solid body of the sun becomes visible, which, not being lucid, gives the appearance of the dark spots or nuclei seen through the telescope. The length of the time during which the spots continue visible renders it evident that the luminous matter of the sun cannot be of a liquid or gaseous nature; for, in either case, the vacuity made by its accidental removal would instantly be filled up, and the uniformity of appearance invariably maintained. Herschel supposed the luminous clouds to be phosphorescent.

Theoretical Astronomy

It would be a needless waste of time to enter into any discussion of a theory so entirely vague and fanciful, and so destitute of all solid foundation. Till we are better acquainted with the nature of light, fire, and heat, and have attained to the knowledge of every possible mode in which these elements can be produced and propagated, all hypotheses respecting the construction of the sun can only be gratuitous and conjectural. Some interesting questions, however, arise out of this subject. Whether the inferior stratum of solar clouds is sufficiently dense, as Herschel imagined, to protect the body of the sun from the scorching effects of the surrounding regions of light and heat, and render it a fit habitation for human beings, is a question of no importance to man, or to any thing pertaining to his planet; but it is interesting for him to know whether the light and heat dispensed by the sun are liable to any variation or secular diminution, either connected with the spots, or resulting from a decrease of the sun's volume.

Uncertainty respecting the constitution of the sun.

Those philosophers who adopt the hypothesis of the production of light and heat by the vibrations of an ethereal fluid, consider the mass of the sun to be invariable. Those, on the contrary, who attribute these effects to an emanation from the sun, think his mass and volume must be diminished by the incessant discharge of torrents of luminous particles from his surface. During the two thousand years which have elapsed since the first astronomical observations, no diminution of the sun's volume has been perceived; but it must be remarked that such an effect may have taken place, though not yet sensible to our instruments. The sun's diameter is nearly 2000″; and at the distance of 95,000,000 miles a second corresponds to 460 miles. Now, supposing the solar diameter to suffer a daily diminution of two feet, which may be considered as enormous, considering the vast magnitude of the sun, and the excessive rarity of light, the diminution would amount to 800 feet in a year, and to 460 miles, or 1″, in 3000 years. Thus, after thirty centuries, the diminution would still be imperceptible, inasmuch as our instruments are not sufficiently accurate to enable us to appreciate, in an observation of this sort, so small a variation as one second.

Mass of the sun undergoes no sensible diminution.

Some astronomers, after Herschel, have imagined that the existence of the solar spots has an influence on the temperature of the seasons. In 1823 the summer was cold and wet; the thermometer at Paris rose only to 23°·7 of Reaumur, and the sun exhibited no spots; whereas in the summer of 1807 the heat was excessive, and the spots of vast magnitude. The relation, however, between the temperature and the appearance of the solar spots is not so uniform as to give much weight to this opinion. Warm summers, and winters of excessive rigour, have happened in the presence or absence of the spots. The year 1783 was remarkable for its fertility and the magnitude of the solar spots; a dry fog enveloped the greater part of Europe, and was followed by the earthquake of Calabria. Another opinion entertained by Herschel was, that one hemisphere of the sun emits less light than the other, so that when viewed at a great distance he will resemble some stars of which the brilliancy is subject to periodical variations.

Connection of the solar spots with the temperature of the seasons.

By reason of the globular figure of the sun, his surface towards the border of the disk is seen obliquely, and therefore a much greater portion of it is comprehend-

Sun supposed to have an atmosphere.

Theoretical Astronomy

ed under a given visual angle, than when the ray proceeds from his centre. Now, as every point of the sun's surface is supposed to emit an equal quantity of light in all directions, it follows that the light ought to be much more intense near the circumference of the disk, because a greater number of rays will proceed from the larger surface, which forms the oblique base of the luminous cone. Bouguer, deceived by some imperfect experiments, thought the light more intense at the centre of the disk than towards the limb; a circumstance which could only be explained by supposing the light to be diminished by some cause which acts most powerfully with regard to the borders of the disk. Such would be the effect of a dense atmosphere surrounding the sun; for in this case the rays which proceed from the border must traverse a much greater extent of the solar atmosphere, and consequently be absorbed in greater proportion than those which proceed from the central parts and traverse it directly; just as the atmosphere of the earth renders the light of the stars at the horizon much feebler than at the zenith. It has been thought, however, that Bouguer's experiments were inaccurate, and that the light is equally intense at the border and the centre. The existence of a solar atmosphere cannot therefore be demonstrated in this manner; but it is clearly indicated by the faint light which is observable round the sun's limb during a total eclipse.

Zodiacal light.

Another very curious phenomenon connected with the sun, is the faint nebulous aurora which accompanies him, known by the name of the *Zodiacal Light.* This phenomenon was first observed by Kepler, who described its appearance with sufficient accuracy, and supposed it to be the atmosphere of the sun. Dominic Cassini, however, to whom its discovery has been generally but erroneously attributed, was the first who observed it attentively, and gave it the name which it now bears. It is visible immediately before sunrise, or after sunset, in the place where the sun is about to appear, or has just quitted, in the horizon. In total eclipses it is seen surrounding the sun's disk, and resembling the beard of a comet. It has a flat lenticular form, and is placed obliquely on the horizon, as represented in fig. 41, the apex extending to a great distance in the heavens. Its direction is always in the plane of the sun's equator, and for this reason it is scarcely visible in our latitudes, excepting at particular seasons, when that plane is nearly perpendicular to the horizon. When its inclination is great, it is either concealed altogether under the horizon, or at least rises so little above it, that its splendour is effaced by the atmosphere of the earth. The most favourable time for observing it is about the beginning of March, or towards the vernal equinox. The line of the equinoxes is then situated in the horizon, and the arc of the ecliptic SS′ S″ (fig. 42) is more elevated than the equator SEQ by an angle of 23½ degrees; so that the solar equator, which is slightly inclined to the ecliptic, approaches nearer to the perpendicular to the horizon, and the pyramid of the zodiacal light is consequently directed to a point nearer the zenith, than at any other season of the year. For example, at the summer solstice, S″T, a tangent to the ecliptic, is parallel to EQ the tangent to the equator, and the luminous pyramid is in a plane less elevated by 23°½ than at the time of the vernal equinox.

Fig. 41.

Fig. 42.

Different opinions regarding the zodiacal light.

Numerous opinions have been entertained respecting the nature and cause of this singular phenomenon. Cassini thought it might be occasioned by the confused light of an innumerable multitude of little planets circulating round the sun, in the same manner as the milky way owes its appearance to the light of agglomerated myriads of stars. Its resemblance to the tails of comets has been noticed by Cassini, Fatio Duillier, and others; and Euler endeavoured to prove that they are both owing to similar causes. Mairan, like Kepler, ascribed it to the atmosphere of the sun; and this hypothesis was generally adopted, till it was shown by Laplace to be untenable for the following reasons. The atmosphere of any planet, endowed with a motion of rotation, cannot extend to an indefinite distance: it can only reach to such a height that the centrifugal force is exactly balanced by the force of gravity. Beyond this height the atmosphere would be dissipated by the superior energy of the centrifugal force. Now the height above the sun at which the two forces are equal is that at which a planet, if placed there, would revolve about the sun in the same time in which the sun performs a revolution on his axis. But the orbit of such a planet would be greatly inferior to the orbit of Mercury; for the time in which Mercury makes a revolution in his orbit is eighty-eight days, while the sun revolves about his axis in twenty-five; it is therefore certain that the atmosphere of the sun cannot extend to the orbit of Mercury. Now, the greatest elongation of Mercury does not exceed 28°, and the zodiacal light has been observed to extend to above 100°, reckoning from the sun to the apex of the luminous pyramid. Hence the phenomenon cannot proceed from the sun's atmosphere. Laplace further remarks, that the ratio of the equatorial and polar axes of the solar atmospherical spheroid cannot exceed that of three to two; whence its form would not correspond with the lenticular appearance of the zodiacal light. But to whatever cause this luminous matter is to be attributed, it is certain that it is of extreme rarity, inasmuch as it does not intercept the light of the smallest stars which are seen through it without any diminution of splendour.

Theoretical Astronomy

On the subject of the solar spots and zodiacal light the following works may be consulted:—Galileo, *Istoria e Dimostrazioni intorno alle Macchie Solari,* Rome, 1613; Scheiner, *Rosa Ursina,* Bracciani, 1630; Hevelius, *Selenographia,* Gedani, 1647; Reutschius, *De Maculis et Faculis Solaribus,* Wittemb. 1661, 4to, Cassini, *Nouv. Observ. des Taches du Soleil;* Hooke, *Tractatus de Maculis Solaribus, et Lumine Zodiacali, in Oper. Posth.* Lond. 1705; Weidler, *De Coloribus Mac. Sol.* in his *Observ. Meteorol.* 1728–9, Wittemb. 1729; Boscovich, *De Mac. Sol.* Rom. 1736, 4to; De Lisle, *Mémoires pour servir à l'Histoire de l'Astr.* Petersb. 1738; Bernoulli, *Lettres Astronomiques,* 1771; Wilson, *Phil. Trans.* 1774, vol. lxiv.; *Ibid.* 1783; Wollaston, *Phil. Trans.* 1774; Lalande, *Phil. Trans.* 1776, *Mém. Acad.* 1776, and *Astronomie,* tom. iii. p. 277; Herschel, *Phil. Par.* tom. vii. p. 119, and viii. p. 193; Mairan, *Traité Physique et Historique de l'Aurore Boreale,* 1731; Lalande, *Astronomie,* tom. i. p. 276; Laplace, *Exposition du Système du Monde*; Delambre, *Hist. de l'Astronomie Moderne,* tom. ii. p. 742.

CHAP. III.

OF THE MOON.

Next to the sun, the moon is to mankind the most important and interesting of all the celestial bodies. Her conspicuous appearance in the heavens, the variety of her phases, and the rapidity with which she changes her place among the fixed stars, have rendered her at all times an object of admiration to the vulgar; while her proximity to the earth, her physical effects on the ocean, the intricacy of the theory of her motions, and the vast importance of that theory to navigation and geography, have equally

Theoretical Astronomy.

claimed the attention of the observer and mathematician; nor is there any other department of astronomy in which their researches have been crowned with more triumphant success, or been rewarded with more brilliant discoveries.

Sect. I.—*Of the Phases, Parallax, and Magnitude of the Moon.*

The different appearances or phases of the moon were probably the first celestial phenomena observed with any degree of attention. When the moon, after having been for some days invisible, is again seen on the eastern side of the sun, and at a distance of 20 or 30 degrees from him, she appears as a curved thread of silvery light; and her form is that of a crescent, the horns of which are turned towards the east. The breadth of the crescent increases continually in proportion as she separates herself from the sun, till, having obtained a distance of 90°, she appears under the form of a semicircle. At this point she is said to be in her *first quarter*. Continuing her motion to the eastward, the line which terminates the eastern side of her disk assumes the curvature of an elliptic arc, and her visible portion continues to increase till she has attained the distance of 180° from the sun, when she appears perfectly round. She is then *full*, and is said to be in *opposition*, rising as the sun sets, and consoling us by her pale light for the absence of the great luminary. Having passed this point, she begins to approach the sun; her western side now takes the form of the elliptic arc, and her luminous portion diminishes exactly in the same proportion as it increased through the first half of her orbit. About seven days after the full she again appears as a semicircle, the diameter of which is turned towards the west, and she is now at her *third quarter*, and at a distance of 90° from the sun. The semicircle after this changes into a crescent, and she continues to approach the sun, till, having advanced to within 20° or 30° from him, she again disappears, being lost in the splendour of his rays. These phases regularly succeed each other, and the time in which they run through all their changes is about 29½ days. When the moon passes the meridian at the same time with the sun, she is said to be in *Conjunction*. The two points of her orbit in which she is situated when in opposition or conjunction are called the *Syzygies;* those which are 90° distant from the sun are called the *Quadratures;* and the intermediate points between the syzygies and quadratures are called the *Octants*.

A slight attention to the lunar phases during a single revolution will be sufficient to prove that they are occasioned by the reflection of the sun's light from the opaque spherical surface of the moon. This fact, which was recognised in the earliest ages, will be made obvious by the help of a diagram. If the moon is an opaque body we can only see that portion of her enlightened side which is towards the earth. Therefore, when she arrives at that point of her orbit A (fig. 43) where she is in conjunction with the sun S, her dark half is towards the earth, and she disappears, as at *a*, there being no light on that half to render it visible. When she comes to her first octant, at B, or has gone an eighth part of her orbit from her conjunction, a quarter of her enlightened side is towards the earth, and she appears horned, as at *b*. When she has gone a quarter of her orbit from her conjunction, to C, she shows us one half of her enlightened side, as at *c*, and we say she is a quarter old. At D she is in her second octant, and by showing us more of her enlightened side she appears gibbous, as at *d*. At E her whole enlightened side is towards the earth, and therefore she appears round, as at *e*, when we say it is full moon. In her third octant, at F, part of her dark side being towards the earth, she again appears gibbous, and is on the decrease, as at *f*. At G we see just one half of her enlightened side, and she appears as a semicircle, as at *g*. At H we only see a quarter of her enlightened side, being in her fourth octant, when she appears horned, as at *h*. And at A, having completed her course from the sun to the sun again, she disappears, and we say it is new moon. Thus, in going from A to E, the moon seems continually to increase; and in going from E to A, to decrease in the same proportion, exhibiting like phases at equal distances from A and E.

Fig. 43.

Theoretical Astronomy.

The magnitude of the visible portion of the moon's disk thus depends on the situation of the moon relatively to the sun and the earth, and is easily determined geometrically from her elongation or angular distance from the sun. Let ADBC (fig. 44) be the projection of the lunar orb on the plane which passes through the centres of the sun, moon, and earth; let S be the place of the sun, E that of the earth, M the centre of the projection, and AB, CD two diameters perpendicular to SM and EM respectively, and let EM meet the circumference in G. It is evident that AGDB represents the hemisphere illuminated by the sun, and CAGD that which is visible from the earth; the whole portion of the visible disk, therefore, is represented by AGD, or by AG and DG. Now, if we conceive the moon's surface to be projected on the plane which passes through her centre perpendicular to the visual ray, the illuminated portion of the disk DG will appear as a semicircle, while the part GA will appear as a semi-ellipse, the minor axis of which is to its major as MF to MC, AF being perpendicular to MC. The eye at E will therefore see the semicircle DMG, together with the semi-ellipse GMA, and the visible part will be to the entire disk as DF : DC, that is, as 1 + sin. AME : 2, or, as 1 + cos. φ : 2; φ being equal to EMS the elongation of the earth from the sun as seen from the moon. The geocentric elongation of the moon from the sun, or the angle MES = ψ, may be substituted instead of φ, when we know the ratio of the distances ES = r and MS = R; for sin. $\varphi = \frac{r}{R}$ sin. ψ, whence cos. $\varphi = \sqrt{1 - \frac{r^2}{R^2} \text{ sin.}^2 \psi}$, and the above proportion becomes

Fig. 44.

$$\text{DF} : \text{DC} :: 1 + \sqrt{1 - \frac{r^2}{R^2} \text{ sin.}^2 \psi} : 2.$$

When the moon is in opposition the angle $\varphi = 0$, whence 1 + cos. $\varphi = 2$, and the whole disk is visible. At the conjunction $\varphi = 180°$, and 1 + cos, $\varphi = 0$; the moon is consequently invisible.

The triangle EMS likewise furnishes the means of finding the distance of the moon when that of the sun is known; or reciprocally, the distance of the sun from that of the moon: but for this purpose it is necessary to observe accurately the limit of illumination, which is not easily done. Let ADBE (fig. 45) be the illuminated part of the moon ACBE. The distance between the cusps A and B, measured by the micrometer, gives the major axis of the ellipse ADB, and the semi-minor axis DM is found by measuring in the same manner the distance ED, and subtracting EM, half the semi-minor AB. This gives $\frac{\text{DM}}{\text{AM}}$ = cos. EMS (fig. 44), and therefore the angle EMS or M; and from SEM, which is given by observation, we have ESM or S = 180° — E — M; whence M and S are given angles; and from the property of the triangle we have EM = ES $\frac{\text{sin. S}}{\text{sin. M}}$, or ES = EM $\frac{\text{sin. M}}{\text{sin. S}}$. The calculation would be greatly facilitated if the observation

Fig. 45.

Theoretical Astronomy.

were made at the exact instant when the moon is dichotomized, or in her first or third quarter, for the elliptic arc then becomes a straight line and the angle EMS=90°; so that sin. M = 1. In this case therefore we have EM = ES sin. S = ES cos. E, and $ES = \frac{EM}{\cos. E}$, which gives the ratio of the distances of the sun and moon. In this manner Aristarchus of Samos attempted to compare the distance of the two luminaries; and although his result was extremely erroneous, inasmuch as he found the distance of the sun to be only between eighteen and twenty times greater than that of the moon, whereas it is actually 380 times greater, yet the idea was an ingenious one, and the method perfectly accurate in theory. The error arose from the inaccuracy of the ancient instruments, and the impossibility of observing to within a few minutes the exact time of the dichotomy. Besides, as the angle at the sun is extremely small, a very slight error either with regard to the time or the angle has a great influence on the result.

Parallax of the moon.

The moon's absolute distance from the earth is obtained by means of her parallax, which, on account of her proximity, is very considerable, and can therefore be determined by the methods which were explained in chap. i. sect. 2. On comparing her parallaxes observed at different times, they are found to differ considerably in value. Thus, according to Lalande, the greatest horizontal parallax at Paris is 61′ 29″, the smallest 53′ 51″; and it assumes every possible value between these two extremes. The horizontal parallax being the angle which the earth's radius subtends at the moon, and consequently equal to the radius of the earth divided by the moon's distance, the perigean and apogean distances corresponding to the extreme parallaxes are respectively 55·916 and 63·842 semidiameters of the earth. The ratio of these two numbers, or of the extreme values of the parallax, is 1·1417, and denotes the greatest variations of the moon's distance from the earth. The ratio of the corresponding quantities in the case of the sun is only 1·034; hence the moon's distance is subject to much greater variations than that of the sun.

These differences in the value of the parallax arise from the variations of the moon's distance from the earth; but it is also observed to differ sensibly at different points of the earth's surface, even at the same instant of time. If the earth were spherical, the horizontal parallax of the moon, supposing her distance to be invariable, would be the same at whatever part of the earth it might be observed. The case is, however, different; for, on account of the spheroidal figure of the earth, the section made by every vertical plane gives a different ellipse, no one of which even passes through the centre of the earth, excepting indeed the cases in which the place of the observer is on the equator or under the pole; for in all other cases the perpendicular to the surface of the earth does not pass through its centre. Hence it is necessary, in speaking of the horizontal parallax, to specify the place of the observation.

Since the parallax of the moon is subject to incessant variation, it is necessary to assume a certain mean value of it, about which the true and apparent values may be conceived to oscillate. This is denominated the *constant* parallax. It is evident that it cannot be found by taking the arithmetical mean of the extreme values; for by reason of the disturbing force of the sun, the eccentricity of the lunar orbit, and consequently the perigean and apogean distances, are constantly varying; and as the quantity by which one of these distances is increased is not equal to that by which the other is diminished, it follows that the mean of the perigean and apogean parallaxes will not be a constant quantity, but different in successive revolutions of the moon. If we abstract from all the inequalities of the lunar orbit, and suppose the moon to be at her mean distance and mean place, the constant parallax will be the angle under which a given semidiameter of the earth is seen by a spectator at the moon in such circumstances. According to Lalande, the following are the values of the constant parallax:—

Under the equator	57′ 5″
Under the pole	56 53·2
For the latitude of Paris	56 58·3
For the radius of a sphere equal in volume to the earth	57 1

Theoretical Astronomy.

Magnitude of the lunar orb.

The mean equatorial parallax being 57′ 5″, its double is 1° 54′ 10″, which expresses the angle subtended by the diameter of the earth at the distance of the moon. The angle subtended by the moon at the same distance is 31′ 26″; whence the diameter of the moon is to that of the earth as 31′ 26″ is to 1° 54′ 10″; that is, as ·524 to 1·903, or as 3 to 11 nearly. According to the tables of Burg, the accurate expression of the above ratio is 1 : 0·27293; hence the true diameter of the moon is 0·27293 diameters of the terrestrial equator. The surface of the moon is consequently $(0{\cdot}27293)^2 = 0{\cdot}0744908 = \frac{1}{13{\cdot}4243}$ of that of the earth, and its volume $(0{\cdot}27293)^3 = 0{\cdot}0203308 = \frac{1}{49{\cdot}1863}$, or, in round numbers, $\frac{1}{49}$th of the volume of the earth.

Sect. II.—*Of the Elements of the Lunar Orbit.*

1. *Nodes and Inclination of the Lunar Orbit.*—A few simple observations of the right ascensions and declinations of the moon suffice to show that her path is confined nearly to a plane, having only a small inclination to the plane of the ecliptic. If her path were rigorously confined to this plane, a single revolution would be sufficient to determine its inclination; but as numerous disturbing causes exist, which produce inequalities in all the elements of the lunar motion, it is only by taking the mean value of a great number of observations that these elements can be astronomically determined. In fixing the position of the plane of the orbit, the first object is to determine the straight line formed by its intersection with the plane of the ecliptic; that is to say, to determine the line of the *Nodes*. This would be at once accomplished if it were possible to observe the instant at which the moon's latitude is nothing; for at this instant her centre is in the plane of the ecliptic, and consequently her longitude is the same as the longitude of the node. But as the accuracy of modern practice requires that all important observations be made in the plane of the meridian, and as it could only happen by a very rare coincidence that the latitude deduced from the meridional right ascensions and declinations would be exactly zero, it is necessary to have recourse to a process of calculation to find the precise place of the node.

Let LNL′ (fig. 46) be a portion of the ecliptic, MNM′ of the lunar orbit, N the place of the node, and ML = λ, ML′ = λ′ be two latitudes on opposite sides of the ecliptic. The two right-angled triangles give, according to Napier's Rules,

Fig. 46.

$$\text{tan. N} = \frac{\text{tan. } \lambda}{\text{sin. NL}} = \frac{\text{tan. } \lambda'}{\text{sin. NL}'};$$

therefore,

$$\frac{\text{sin. NL}'}{\text{sin. NL}} = \frac{\text{tan. } \lambda}{\text{tan. } \lambda'};$$

whence,

$$\frac{\text{sin. NL} - \text{sin. NL}'}{\text{sin. NL} + \text{sin. NL}'} = \frac{\text{tan. } \lambda - \text{tan. } \lambda'}{\text{tan. } \lambda + \text{tan. } \lambda'};$$

Theoretical Astronomy

that is, by the trigonometrical formulæ,

$$\frac{\tan.\frac{1}{2}(NL-NL')}{\tan.\frac{1}{2}(NL+NL'} = \frac{\sin.(\lambda-\lambda')}{\sin.(\lambda+\lambda')}$$

$$\text{or } \tan.\tfrac{1}{2}(NL-NL') = \tan.\tfrac{1}{2}LL' \cdot \frac{\sin.(\lambda-\lambda')}{\sin.(\lambda+\lambda')}.$$

Having therefore obtained an expression for the difference of NL and NL′, and knowing also their sum LL, which is the difference of the longitudes of the moon at the time of the two observations, it is easy to deduce NL or NL ; consequently the longitude of the node is determined.

The *Ascending Node* of the lunar orbit is that point of the ecliptic through which the moon passes when she rises above the ecliptic towards the north pole: it is distinguished by the character ☊. The *Descending Node*, ☋, is the opposite point of the ecliptic, through which she passes when she descends below that plane towards the south pole. The nodes of the lunar orbit were anciently called the head and tail of the Dragon.

The position of the nodes is not fixed in the heavens. They move in a retrograde direction, or contrary to the order of the signs; and their motion is so rapid that its effects become very apparent after one or two revolutions. Regulus, a star of the first magnitude, is sometimes eclipsed by the moon; and as the latitude of this star is only about 27′ or 28′, it is certain that when that phenomenon occurs the moon is very near her node. Suppose it to be the ascending node: the month following it will be observed that the moon passes to the north of Regulus; and every succeeding month she will pass farther to the north of the same star, till at the end of four or five years, when her meridional altitude will be about 5° greater than that of Regulus. Her latitude on passing Regulus now begins to diminish; and, after a period of about nine years, Regulus is again eclipsed by the moon in her descent to the southern side of the ecliptic. The moon after this passes to the south of the star for the following nine years; and at the end of 18½ years the nodes have returned to their first position, after accomplishing a complete revolution. The same result is found from the observation of eclipses, the magnitude of which depends on the moon's latitude; and therefore, if the nodes remained fixed, the eclipses would always be of the same magnitude in the same quarter of the heavens. This, however, is not the case; and it is only after about 18½ years that they begin to return in the same order.

The mean retrograde motion of the nodes is found, by the comparison of observations made at distant epochs, to amount to 19° 19′ 42″·316 in a mean solar year, and the time in which they make a tropical revolution is consequently 6798·179 mean solar days. The longitude of the ascending node on the 1st of January 1801 was 13° 53′ 17″·7; hence its position at any other epoch is easily deduced, since we know the rate of its mean motion.

The inclination of the lunar orbit may be determined either by observing the moon's greatest latitudes, or it may be computed from the formula, $\tan. N = \frac{\tan \lambda}{\sin. NL}$, when her latitude and longitude are known. The angle N, or the inclination, is observed to vary between 5° and 5° 17′ 35″. The mean inclination may therefore be taken at 5° 8′ 48″.

The retrograde motion of the moon's nodes, as well as all the other inequalities of the lunar motion, is occasioned by the attracting power of the sun, which varies in intensity according to the positions of the earth and moon in their orbits. The principal inequality to which the inclination of the lunar orbit is subject, is proportional to the cosine of double the sun's distance from the moon's ascending node. In fact, the sun and earth being always in the plane of the ecliptic, when the moon is also in that plane the action of the sun will have no tendency to increase or diminish her latitude; it will only affect her radius vector, or distance from the earth. But if the moon is not in the plane of the ecliptic, the sun's attracting force will not only affect her distance from the earth, but also tend to bring her nearer to the ecliptic; and this action will be greater in proportion to her deviation from that plane. When the nodes are in quadratures, and the limits of latitude in the syzygies, the inclination is 5°, as was found by Ptolemy; but when the nodes are in the syzygies, and the limits in quadratures, the inclination is 5° 17′ 35″. It has therefore a mean value of 5° 8′ 48″, when the nodes and limits coincide with the octants. Denoting therefore the greatest deviation from the mean values by x, this deviation will pass through all its values between $+ x$ and $- x$ while the sun's distance from the ascending node varies from 0° to 90°. It may therefore be represented by a function which varies as the cosine of twice that distance, for the cosine of an angle runs through all its changes from + 1 to — 1 between 0 and 180°. Hence the equation which expresses the principal inequality of the moon's latitude is

(8′ 47″) cos. 2 ⊙'s distance from ☽'s ☊.

The co-efficient 8′ 47″ is called, in astronomy, the *Co-efficient of the Argument*, the argument itself being the function by which the inequality is represented.

This periodic inequality of the moon's latitude was discovered by Tycho Brahe, from a comparison of the greatest latitudes at different epochs with the correponding positions of the moon with reference to her nodes. He observed that these latitudes oscillate about the mean value of 5° 8′ 48″; and as the greatest latitudes give immediately the inclination of the moon's orbit to the plane of the ecliptic, it necessarily followed that the inclination is subject to similar variations. The motion of the node of the lunar orbit is also subject to an inequality, depending on the same angle as the preceding, but proportional to its sine. Tycho explained these two inequalities by a very simple hypothesis, similar to that by which we have explained the oscillations of the terrestrial equator, namely, a slight nutation of the earth's axis. In the present case it is only necessary to place the mean pole of the lunar orbit at the distance of 5° 8′ 48″ from the pole of the ecliptic, and to suppose the true pole to describe a small ellipse about the mean pole in the same time that the sun occupies in making a semi-revolution with regard to the nodes of the moon's orbit, that is, in 173·309 days.

There are various other inequalities which affect the latitude of the moon and the inclination of her orbit, to correct which, a large number of equations are given in the recent and most accurate tables. The greater part of them are, however, only known from theory, and are so small that even their accumulated effects are scarcely perceptible to observation.

Phenomenon of the harvest-moon.

The inclination of the lunar orbit to the plane of the terrestrial equator occasions considerable differences in the intervals between the moon's rising or setting on successive days, and gives rise to the phenomenon of the *Harvest Moon*. As the daily motion of the moon is about 13 degrees from west to east, it follows that if she moved in a plane parallel to the equator, she would rise 50 minutes later every successive evening, because her orbit would then make the same angle with the horizon at all seasons of the year, and the intervals between her consecutive risings would be constant. For the sake of explanation, we may here suppose the moon to move in the plane of

Theoretical Astronomy.

the ecliptic. Now, the time in which a given arc of the ecliptic rises above the horizon depends on its inclination to the horizon. In our latitudes the inclination of the ecliptic at different points to the horizon varies so much, that at the first point of Aries an arc of 13° becomes visible in the short space of 17 minutes, while at the 23d of Leo the same arc will only rise above the horizon in one hour and 17 minutes. Hence, when the moon is near the first point of Aries, the difference of the times of her rising on two successive evenings will be only about 17 minutes; and as this happens in the course of every revolution, she will rise for two or three nights every month at nearly the same hour. But the rising of the moon is a phenomenon which attracts no attention, excepting about the time when she is full, that is, when she rises at sunset. In this case she is in opposition to the sun, and consequently, if she is in Aries, the sun must be in Libra, which happens during the autumnal months. At this season of the year, therefore, the moon, when near the full, rises for some evenings at nearly the same hour. This circumstance affords important advantages to the husbandman, on which account the phenomenon attracts particular attention.

It is obvious, that as this phenomenon is occasioned by the oblique position of the lunar orbit with regard to the equator, the effect will be greater than what has just been described if the plane of that orbit makes a greater angle with the equator than the plane of the ecliptic does. But we have seen that the plane of the moon's orbit is inclined to the ecliptic in an angle exceeding 5°; consequently, when her ascending node is in Aries, the angle which her orbit makes with the horizon will be 5° less than that which the ecliptic makes with the horizon; and the difference of time between her risings on two successive evenings will be less than 17 minutes, as would have been the case had her orbit coincided with the ecliptic. On the contrary, when the descending node comes to Aries, the angle which her orbit makes with the horizon will be greater by 5°, and consequently the difference of the times of her successive risings will be greater than if she moved in the plane of the ecliptic. If when the full moon is in Pisces or Aries the ascending node of her orbit is also in one of those signs, the difference of the times of her rising will not exceed one hour and forty minutes during a whole week; but when her nodes are differently situated, the difference in the time of her rising in the same signs may amount to $3\frac{1}{2}$ hours in the space of a week. In the former case the harvest-moons are the most beneficial, in the latter the least beneficial, to the husbandman. All the variations in the intervals between the consecutive risings or settings take place within the period in which the line of the nodes makes a complete revolution.

2. *Dimensions, Eccentricity, and Apsides of the Lunar Orbit; and the Inequalities of the Moon's motion.*—Since the moon moves in a plane orbit, the projection of her path on the surface of the celestial sphere will be a great circle. But the variations observable in the magnitude of her apparent diameter, and in the velocity of her motion, prove that if her orbit is a circle, the earth is at least not placed at its centre. The numerous perturbing causes which affect her motion render the exact determination of her orbit a matter of great difficulty; but observation shows that it deviates very little from an ellipse, of which the centre of the earth occupies one of the foci. It has also been found that the spaces passed over by the radius vector of the moon are very nearly proportional to the times of description; which is the distinctive character of the elliptic motion.

Theoretical Astronomy.

In order to obtain a correct idea of the figure and position of the orbit, it is necessary to know its major axis, its eccentricity, and the position of its apsides. The major axis is equal to the sum of the greatest and least distances, and these have already been stated to be respectively 63·842 and 55·916 semidiameters of the earth; whence, supposing the earth's radius to be 4000 miles, the major axis of the lunar orbit will amount in round numbers to 480,000 miles. It may be here remarked that the moon's distance is an element which may be practically determined with great exactness. A variation of 1″ in the parallax would occasion an error of only about 67 miles in the determination of the distance; therefore, since the parallax is certainly known to within 4″, the greatest error in the distance deduced from it cannot exceed 280 miles out of about 240,000 miles.

An approximation to the eccentricity of the orbit of the moon is easily obtained from the variations of her apparent diameter. The moon's apparent diameter is observed to vary between 29′ 30″ and 33′ 30″ very nearly. Now, let D denote the mean, D′ the apogean, D″ the perigean diameter, and e the eccentricity. We shall then have

$$D' = \frac{D}{1+e} = 29'\ 30'',$$

$$D'' = \frac{D}{1-e} = 33'\ 30'',$$

$$\frac{D'}{D''} = \frac{1-e}{1+e} = \frac{29'\ 30''}{33'\ 30''};$$

whence we deduce

$$e = \frac{33'\ 30'' - 29'\ 30''}{33'\ 30'' + 29'\ 30''} = \frac{4}{63} = 0{\cdot}0635.$$

This eccentricity corresponds to an equation of the centre amounting to 7° 16′, and is much more considerable than that of the solar orbit, which, as we have before seen, amounts only to 0°·0168. The result just given is, however, only to be considered as approximative, and is, in fact, considerably too large. In the best and most recent tables the value assigned to the eccentricity of the lunar orbit is 0·0548442, and the corresponding equation of the centre 6° 17′ 12″·7. (See *Astronomical Tables and Formulæ*, by Francis Baily, Esq. London, 1827.)

The place of the apsides is likewise found from observations of the moon's apparent diameter, because at these points of the orbit the apparent magnitude has its maximum and minimum values. But as the apparent magnitude varies very slowly at the apsides, it is preferable, as Lalande remarks, to choose the points of mean distance where its variations are most rapid. Having selected two observations which give the same apparent diameter at two opposite points of the orbit, we shall have two points evidently at equal distances from the perigee, the longitude of which will therefore be given at the middle time between the two observations. In comparing the positions of the apsides thus determined at different epochs, it is found that they have a rapid progressive motion, that is, according to the order of the signs. In Mr Baily's tables the motion of the perigee is stated to be 4069°·046278, or 11 revolutions + 109° 2′ 46″·6, in 36525 mean solar days. Its mean motion in a mean solar day is consequently 6′ 41″; and in 365 mean solar days, 40° 39′ 45″·36. Hence the time in which it completes a sidereal revolution is 3232·575343 mean solar days. The period of a tropical revolution of the apsides is 3231·4751 mean solar days = 3231 days, 11 hours, 24 minutes, 0·8 seconds, or nearly 9 years. This mean motion of the lunar apsides is, however, subject to periodic inequalities of considerable magnitude, and therefore can only be determined accurately by means of observations separated from

each other by a long interval of time. In the tables just quoted, the epoch is the commencement of the present century, when the longitude of the perigee was in 266° 10′ 7″·5. From this and the rate of the mean motion, the mean longitude of the perigee at any other epoch may be easily computed.

Inequalities of the lunar orbit.

If the moon's place in her orbit were not subject to the influence of any disturbing force, her true longitude, or distance from the apsis, would be found at any instant from the theory of the elliptic motion, supposing her mean motion, or the time of a return to the same perigee or apogee, to be accurately known. Thus, supposing E to denote the maximum elliptic equation, which, as we have already stated, amounts to 6° 17′ 12″·7, we should have the true longitude = mean longitude + E sin. A, A being the moon's mean anomaly, and the longitudes counted from the perigee. This first equation or correction of the mean motion results solely from the circumstance that the moon moves in an elliptic orbit, according to the laws of Kepler, in the same manner as the sun and all the planets. Its argument is the mean anomaly A, and its period the anomalistic month. But the moon's longitudes, as determined in this manner, are far from agreeing with observation; and several other corrections must be applied, the accurate determination of which forms the principal object of the lunar theory.

Equation of the centre.

Evection.

After the equation of the centre, the most considerable of the inequalities of the moon's longitude is that to which Boulliaud gave the name of the *Evection*. It was noticed by Hipparchus; but it was Ptolemy who discovered its law, and gave a construction which represents its general effects with great accuracy. These effects are to diminish the equation of the centre when the line of the apsides lies in syzygy, and to augment it when the same line lies in quadratures. Thus, supposing the apsides to lie in syzygy, and that it is sought to compute the moon's true longitude about seven days after she has left the perigee, by adding the equation of the centre to the mean anomaly, the resulting longitude will be found to be above 80′ *less* than that which is given by observation. But if the line of the apsides lies in quadratures, the place of the moon at about the same distance, that is, 90° from the perigee, computed in the same manner, will be found to be before the observed place by above 80′; that is, the computed will be *greater* than the observed longitude, by more than 80 minutes. After a long series of observations, astronomers have found that the inequality in question is represented with great exactness, by supposing it proportional to the sine of twice the mean angular distance of the moon from the sun, minus the mean anomaly of the moon. In Baily's tables, its maximum value is stated to be 1° 20′ 29″·9; whence, representing the angular distance of the sun and moon by ☽ — ☉, and the mean anomaly as before by A, the correction due to the evection will be

(1° 20′ 29″·9) sin. [2(☽ — ☉) — A].

Variation.

A third inequality of the lunar motion, called the *Variation*, was discovered by Tycho Brahe, who found that the moon's place, calculated from her mean motion, the equation of the centre, and the evection, does not always agree with the true place, and that the variations are greatest in the octants, or when the line of the apsides makes an angle of 45° with that of the syzygies and quadratures. Having observed the moon at different points of her orbit, he found that this correction has no dependence on the position of the apsides, but only on the moon's elongation from the sun. Its maximum value is additive in the octants which come immediately *after* the syzygies, where the elongation is 45°, or 180° + 45°, and subtractive in the octants which *precede* the syzygies, where the elongation is 360° — 45°, and 180° — 45°. It vanishes altogether in the syzygies and quadratures where the elongation is 0°, 180°, 90°, or 270°; and on this account it was not perceived by the ancient astronomers, who only observed the moon in those positions. It will be readily perceived, from the limits between which it varies, that it is proportional to the sine of twice the angular distance between the sun and moon. Its maximum value, or the co-efficient of its argument, is 35′ 41″·9; hence the correction necessary on account of it is represented by the formula

(35′ 41″·9) sin. 2 (☽ — ☉).

Annual equation.

When this equation is added to the two preceding ones, the differences between the computed and observed places of the moon are brought within narrower limits; but they do not yet disappear altogether except in the months of June and December, and about the time of the equinoxes they are found to amount to eleven or twelve minutes. This inequality was observed by Tycho and Kepler, though neither of them determined its magnitude. They supposed it to be an equation of time peculiar to the moon; and under this form Horrox inserted it in his tables, assigning its maximum value at 11′ 16″, which differs only by four seconds from that which is obtained from the most accurate modern observations. On account that it is regulated by the seasons, and depends not on the lunar orbit, but the anomaly of the sun, Kepler gave it the name of the *Annual Equation*. By reason of this inequality the motion of the moon is slower than the mean motion during the winter months, when the motion of the sun is most rapid; and, on the contrary, is most rapid in summer, when the sun's motion is slowest. Hence its argument is the same as that of the equation of the centre of the sun, but with a contrary sign. It is therefore proportional to the sine of the sun's mean anomaly; its period is the anomalistic year, and its maximum value is found by observation to be 11′ 11″·9; hence it is expressed by the formula

(11′ 11″·9) sin. ☉'s mean anomaly.

If we now collect these equations we shall obtain the following corrected expression of the moon's true place:

☽'s true longitude = ☽'s mean longitude,

+ (6° 17′ 12″·7) sin. A
+ (1° 20′ 29″·9) sin. [2(☽ — ☉) — A]
— (35′ 41″·9) sin. 2 (☽ — ☉)
— (11′ 11″·9) sin. ☉'s mean anomaly.

For the physical cause of the three last-mentioned inequalities, viz. the evection, the variation, and the annual equation, see *Physical Astronomy*, sect. ii. par. 37, 38, and 39. They are the principal but not the only periodic inequalities which affect the longitude of the moon; for the profound investigations of modern science have detected many others, which, by reason of their small values, and the manner in which they are blended with one another, would have eluded all attempts to discover their period or their law by observation alone. Observation can make known only the joint effect of the independent equations, and thereby indicate their existence. In order to separate them and determine their respective values, it is indispensable to have recourse to the physical theory, from which alone the various circumstances of the lunar motion can be properly determined. Newton was the first who attempted to compute *a priori* the inequalities of the moon's motion, and thereby led the way in a research which was prosecuted with infinite ingenuity and profound analytical skill by D'Alembert, Clairaut, Euler, and other illustrious mathematicians of the last century, and which was only brought to a successful termination by the labours of Laplace. The formulæ given in the seventh

book of the *Mécanique Céleste*, for a great number of new inequalities derived from the theory of attraction, form the basis of the lunar tables of Burg and Burckhardt. It is to these theoretical researches that we are indebted for the precision with which the moon's motion is actually known, and the great advantages which thence result to geography and navigation. The recent tables contain no fewer than twenty-eight equations of longitude, all which may be regarded as corrections of the mean values of the four which we have explained, and which are themselves corrections of the mean motion. It is thus that astronomy approaches nearer and nearer, by every successive step, to the last term of a series which would represent the orbits and motions of the celestial bodies with absolute accuracy.

Acceleration of the mean motion of the moon.

The lunar inequalities which we have as yet considered are all of a periodic nature, are compensated in the course of a comparatively small number of years, and have passed through many complete revolutions since the commencement of the history of astronomical observations. But there are, as in the case of the sun, others of a different kind, the periods of which are so long that, with reference to the duration of human life, they may be considered as permanently affecting the elements of the lunar orbit. These are the *Secular Inequalities*, the most remarkable of which is the acceleration of the moon's mean motion.

On comparing the lunar observations made within the last two centuries with one another, there results a mean secular motion greater than that which is given by comparing them with those made by Ebn-Jounis, near Cairo, towards the end of the 10th century, and greater still than that which is given by comparing them with observations of eclipses made at Babylon in the years 719, 720, and 721 before our era, and preserved by Ptolemy in the *Almagest*. These comparisons, which have been made by different astronomers with the utmost care, prove incontestably the acceleration of the motion of the moon from the Chaldeans to the Arabians, and from the Arabians to the present times.

The acceleration of the moon's mean motion was first remarked by Dr Halley, and mentioned in his *Notes* on the observations of Albategnius, inserted in the *Philosophical Transactions* for 1693. It was fully confirmed by Dunthorne, who was led by the discussion of a great number of ancient observations of eclipses, to suppose that it proceeded uniformly at the rate of 10″ in a hundred years; a supposition which consequently gave him a correction for the mean longitude of the moon proportional to the square of the time, or of 10″ multiplied by the square of the number of years elapsed between 1700 and the epoch of the calculation. This was the first attempt to estimate the value of the secular equation, which had hitherto been confounded with the mean secular motion. By a similar discussion of ancient observations, Mayer was likewise led to a secular equation proportional to the square of the time, which, in his first *Lunar Tables*, published in 1753, he valued at 7″ for the first century, counting from the year 1700, but which he advanced to 9″ in his last tables, published in 1770. Lalande found it to amount to 9″·886, and therefore agreed with Dunthorne in estimating the acceleration at 10″ for the first century after 1700. Delambre subsequently undertook to determine accurately the actual motion of the moon in a century, from a comparison of the best modern observations. He found it to amount to 307° 53′ 9″ (rejecting the circumferences), while the most ancient observations agree in making it less by 3 or 4 minutes. The equation, which, in consequence of these comparisons, was empirically introduced into the tables, has been confirmed by the theory of gravitation; and the discovery of the physical cause, and of the law of the acceleration, due to Laplace, forms one of the most brilliant triumphs of modern science. In 1786 Laplace demonstrated that the acceleration is one of the effects of the attraction of the sun, and connected with the variations of the eccentricity of the earth's orbit in such a manner that the moon will continue to be accelerated while the eccentricity diminishes, but that it will disappear when the eccentricity has reached its maximum value; and when that element begins to increase, the mean motion of the moon will be retarded.

In order to take into account the effects of the acceleration in the determination of the mean longitude, M. Damoiseau has given the following formula for the secular variation; $10''{\cdot}7232\,n^2 + 0''{\cdot}019361\,n^3$, where n is the number of centuries from 1801; so that if L is the mean longitude of the moon on the 1st of January 1801, and m is the secular motion at that epoch, the mean longitude will be $L + mn + 10''{\cdot}7232\,n^2 + 0''{\cdot}019361\,n^3$ after n centuries. By means of this equation the tables satisfy the most ancient observations, and may be extended to at least a thousand years from the present epoch. It is only necessary to observe, that, in applying the formula, n must be taken negatively, if the epoch is anterior to 1801.

Secular inequalities of the perigee and nodes.

The same cause which gives rise to the acceleration of the mean motion, namely, the diminution of the eccentricity of the earth's orbit, also occasions secular inequalities in the motion of the perigee and nodes of the orbit of the moon. These two inequalities are, however, affected with opposite signs to that of the former; that is, while the mean motion of the moon is accelerated, the motion of her perigee and that of her nodes are retarded. They were deduced by Laplace from theory, and the equations by which they are expressed are connected with one another by a very simple proportion. If we take A to represent the secular acceleration of the mean motion, the secular variation of the perigee found by Laplace is — 4·00052 A, and that of the nodes — 0·735452 A. From this Laplace concluded that the three motions of the moon, with respect to the sun, to her perigee, and to her nodes, are accelerated, and that their secular equations are in the ratio of the above numbers. By pushing the approximations to a great length, MM. Plana and Carlini, and M. Damoiseau, in *Memoirs* which obtained the prize of the Academy of Sciences for 1820, have found different numbers; those of Damoiseau are 1, 4·702, and 0·612. These important results of theory are all confirmed by observation.

The three secular inequalities which have been pointed out will obviously occasion others; for all quantities depending on the mean motion, the motion of the perigee, or of the nodes, must be in some degree modified by them. Thus the mean anomaly, which is the difference of the mean longitude of the moon and the mean longitude of the perigee, is subject to a secular equation equal to the difference of the secular equations affecting the longitudes of the moon and the perigee. The radius vector, the eccentricity and inclination of the orbit, are affected by the secular inequality of the mean motion, which, although too minute to have been hitherto appreciable, will acquire sensible values in the course of ages. The major axis of the ellipse is the only element exempted from inequalities of this sort. It is not probable, however, that the utmost efforts of science will ever make us acquainted with all the irregularities to which the moon's motion is subject. They can only be developed by the complete integration of the differential equations of motion; an integration which is laboriously performed term by term, and which, when attempted to be carried beyond a certain point, transcends

Theoretical Astronomy.

the limits of human patience and industry. What is most essential is to select, among the multitude of terms, such as may possibly acquire considerable co-efficients by integration.

The following table (extracted from Baily) exhibits in one view the different elements of the lunar orbit. The epoch is the commencement of the present century.

Mean inclination to the plane of the ecliptic	5°	8′	47″·9
Longitude of ascending node	11	53	17 ·7
Motion of node in 365 mean solar days	19	19	42 ·316
Longitude of perigee	266	10	7 ·5
Mean motion of perigee in 365 mean solar days	40	39	45 ·36
Mean [illegible]	118	17	8 ·3
Greatest equation of the centre	6	17	12 ·7
Eccentricity	0·0548442		
Mean distance from the earth in diameters of the terrestrial equator	29·982175		

SECT. III.—*Of the different Species of Lunar Months.*

In treating of the sun, we took notice of three different species of revolutions or years, namely, the mean solar year, or the interval of time which the sun employs in performing a complete revolution with regard to the equinoxes; the sidereal year, or the time in which he returns to the same fixed star; and the anomalistic year, or the time in which he returns to the same point of his ellipse. In like manner, if we understand by the term *month* the time which the moon employs to make an entire revolution relatively to any given point, moveable or fixed, we shall have as many different species of months as there are different motions with which that of the moon can be compared. For example, if we estimate her revolution relatively to the sun, the month will be the time which elapses between two consecutive conjunctions or oppositions. This is called the *synodic month*, *lunar month*, or *lunation*. If we consider her revolution as completed when she has gone through 360° of longitude counted from the moveable equinox, we shall have the *tropical* or *periodic month*. The interval between two successive conjunctions with the same fixed star is the *sidereal month*. A revolution with regard to the apsides of her orbit, that is to say, the time in which she returns to her perigee or apogee, gives the *anomalistic month*: and, finally, the revolution with regard to the nodes is the *nodical* or *draconitic month*.

Of these different periods the most important to mankind is the synodic month. It is also that which, by reason of the striking manner in which it is marked out by the phases of the moon, would first offer itself to the attention of the observer; and when its period is accurately determined, the other months may be deduced from it without difficulty, when the relative motions of the sun and moon are known with sufficient precision. The eclipses furnish a simple means of determining the synodic revolution with a great degree of accuracy. A few rude observations suffice to show that the period of a lunation is very nearly 29½ days; and with this knowledge we are in a condition to compare two distant eclipses without running any risk of mistaking the number of revolutions that have taken place in the interval. One of the oldest observations recorded by Ptolemy is an eclipse of the moon, which happened 720 years B. C., on the 19th of March, at 6 hours 48 minutes mean time at Paris, according to Lalande. In order to make use of this observation directly for the purpose of determining the synodic revolution, it is necessary to compare it with another of the same kind in which the moon occupied the same point of her ellipse, or the same position relatively to her apsides; for as it is the *true* place of the moon which is observed, and the *mean* motion which we are in quest of, the equation of the centre ought to be the same in both observations. Now, a similar observation is furnished by an eclipse which happened in 1717, on the 9th of September, at 6 hours 2 minutes, the moon's anomaly being very nearly the same as in the Babylonian observation. In the interval between the two observations the moon had therefore completed a whole number of revolutions, with regard to her mean as well as her true motion. The interval between the eclipses is 2437 years and 174 days minus 46 minutes, which expressed in days is 890287·9680555 days. In this interval it is found, from the approximate value of 29½ days, that 30148 synodic revolutions had happened; hence the mean length of the synodic month is $= \frac{890287{\cdot}968055}{30148} = 29$ days 12 hours 44 min. 2·8497 sec.

Theoretical Astronomy.

To deduce the other revolutions, let N = the number of days in a synodic month, n the number of synodic revolutions in the interval between the two observations, m the mean motion of the sun, and T the time of a tropical revolution. We shall then have the proportion $T : N :: 360° : n \times 360° + m$; whence

$$T = \frac{N \times 360°}{n \times 360° + m} = \frac{N}{n + \frac{m}{360°}} = \frac{\left(\frac{N}{n}\right)}{1 + \frac{m}{n \times 360°}}$$

$$= \frac{N}{n}\left\{1 - \frac{m}{n \times 360°} + \left(\frac{m}{n \times 360°}\right)^2 - \&c.\right\}.$$

Let S = the time of a sidereal revolution. The value of S is immediately found from T; for let p = the precession of the equinoxes in the time T, we shall have $S : T :: 360° : 360° - p$; whence

$$S = \frac{T \times 360°}{360° - p} = \frac{T}{1 - \frac{p}{360°}}.$$

$$= T\left\{1 + \frac{p}{360°} + \left(\frac{p}{360°}\right)^2 + \&c.\right\}.$$

In like manner, if we represent by u the motion of the apside, and by v that of the node, in the time T, the times of the anomalistic and nodical revolutions will be respectively obtained by the substitution of u and $-v$ (the motion of the node being retrograde) in the last formula in place of p. Instead, however, of proceeding in this manner, it is better to assume as the basis of the calculation the mean motion of the moon in longitude, which is accurately known by the observations of 2000 years, and thence to deduce the time of the mean tropical revolution.

The mean motion of the moon in 100 Julian years, or 36525 days, is found to be 1336 circumferences + 307° 52′ 43″·5; or, by reducing the degrees, &c. to the fraction of a circumference, 1336·85521875 circumferences. The periodic month is therefore $\frac{35625}{1336{\cdot}85521875}$ days. In order to reduce the denominator of this fraction to a smaller number of digits, we may divide its terms by 3, multiply them by 32, then divide them by 900, and there will result $\frac{432{\cdot}888\ldots}{15{\cdot}84421}$, the denominator of which contains only 7 digits in place of 12. On performing the division, we shall find the periodic month or tropical revolution = 27·321582388 days = 27 days 7 hours 43 min. 4·7183 sec.

Theoretical Astronomy

The mean motion of the moon in 36525 days is.....1336° 307° 52′ 43″·5
that of the sun.....100 0 45 45

hence the relative motion is.....1236° 307° 6′ 58″·5 = 445267·11625 degrees. The time of a synodic revolution is therefore $\frac{360 \times 36525}{445267{\cdot}11625}$ days; or, multiplying numerator and denominator by 800, $= \frac{10519200000}{356213693}$; whence the synodic month is 29·5305885391 days = 29 days 12 hours 44 min. 2·849778 sec.

In order to obtain the sidereal revolution, we subtract the secular motion of the equinoctial points = 5010″ = 1° 23′ 30″ from the moon's tropical revolution; the remainder, which gives the sidereal motion of the moon in 36525 days, is 1336° 306° 29′ 13″·5 = 481266·4870833 degrees. Hence the time of a sidereal revolution is $\frac{360 \times 36525}{481266{\cdot}4870833}$ days. On multiplying the terms of this fraction by 2400, it is reduced to $\frac{31557600000}{1155039569}$, which gives the sidereal month = 27 days 7 hours 43 min. 11·544375 sec.

In like manner, by subtracting the motion of the perigee in 100 years from the secular motion of the moon, we shall find the anomalistic revolution to be 27 days 13 hours 18 min. 34·9488 sec.; and by adding the retrograde secular motion of the node to the secular motion of the moon, the revolution in respect of the nodes is found to be performed in 27 days 5 hours 5 min. 35·60769 sec.

The following table exhibits the different kinds of lunar periods and motions:—

	Days.	Ho.	Min.	Sec.	Days.
Synodic revolution	29	12	44	2·84 =	29·5305887
Tropical	27	7	43	4·71 =	27·3215824
Sidereal	27	7	43	11·54 =	27·3216614
Anomalistic	27	13	18	37·40 =	27·5545995
Nodical	27	5	5	35·60 =	27·2122176
Tropical revolution of node	6798	4	17	43·18 =	6798·1789720
Sidereal	6793	6	59	15·34 =	6793·2911498

☾'s mean tropical daily motion.....13° 10′ 35″·027
☾'s mean sidereal daily motion.....13° 10′ 34″·889
☾'s daily motion in respect of node.....13° 13′ 45″·534

According to Ptolemy, the synodic month is 29 days 12 hours 44 min. 3⅓ sec., which differs from the above only by half a second. The same great astronomer made the tropical month to consist of 27 days 7 hours 43 min. 7¼ sec., which exceeds the true time by 2½ seconds; an error into which he was led by assigning too great a value to the mean motion of the sun.

The ancient astronomers paid great attention to these different revolutions, for the purpose of regulating their lunisolar calendar, and of avoiding the calculation of eclipses, which is attended with difficulties that to them must have proved almost insuperable. Their object was therefore to assign composite periods, after the revolution of which the eclipses would again return in the same order. Now, it is easy to see that a period which will bring back eclipses of the same magnitude and duration, on the same day of the year and at the same longitude, must be an exact multiple of the different lunar months. The return of the moon to the same distance from her node will give an eclipse of the same magnitude; if she returns at the same time to the same point of her orbit, the eclipse will also be of the same duration; and if, in addition to these circumstances, she has also returned to the same longitude, the eclipse will take place on the same day of the year. But the numbers in the above table being incommensurable, it is impossible to find any period, however long, that will embrace all these conditions; the ancients therefore formed periods of different lengths, according as they aimed at satisfying the different conditions with a greater or less degree of precision. For an account of some of the most remarkable of the ancient lunisolar periods, see CALENDAR.

Theoretical Astronomy

On account of the acceleration of the mean motion of the moon, the ratios of the different species of months are constantly undergoing alterations, and therefore the different cycles, supposing them exact at the time of their formation, cannot continue so for an indefinite length of time. This circumstance is, however, little to be regretted; for, in the present state of astronomical science, they are not of any great use, inasmuch as we are in possession of surer methods of predicting eclipses, the calculation of which, from the ephemerides, is now a matter of comparative facility. They are, however, interesting in an historical point of view, and their formation was a principal object of the labours of the early astronomers. (On this subject, see Lalande, *Astronomie*, tome ii. p. 185; Delambre, *Astronomie Théorique et Pratique*, tome ii. p. 319; Schubert, *Traité d'Astronomie Théorique*, tome ii.; Woodhouse's *Astronomy*, p. 665.)

SECT. IV.—*Of the Rotation and Libration of the Moon.*

On account of the proximity of the moon to the earth, the surface of that body is far better known to us than that of any other of the solar system, and in proportion to the increase of optical power which is brought to bear upon it, delineations of the mountains and volcanic craters that occupy the greater portion of it become more minute and accurate. As seen through a good telescope, the dark patches visible with the naked eye assume the appearance of mountainous inequalities, prodigiously increased in number, and with every possible variety of outline. These present no changes of form like those of the sun, but permanently exhibit the same uniform appearances, and retain their relative situations with regard to each other, and also, with some slight variations, to the apparent centre of the moon. The moon, therefore, at all times presents very nearly the same face to the earth. But if this were rigorously the case, it would follow that the moon revolves about an axis, perpendicular to the plane of her orbit, in the same time in which she completes a sidereal revolution about the earth, and that the angular velocities of the two motions are exactly equal. It is, however, proved by observation, that there are some variations in the apparent position of the spots on the lunar disk. Those which are situated very near the border of the disk alternately disappear and become visible, making stated periodical oscillations. But as they suffer no sensible changes in their relative positions, and always re-appear under the same form and magnitude when they return to the same position, it is inferred that they are permanently fixed to the surface of the moon; and their oscillations consequently seem to indicate a sort of vibratory motion of the lunar globe, which is known by the appellation of its *libration*. This motion has, however, no real existence. The phenomenon is the complicated result of several optical illusions, and does not depend in any degree on the rotation of the moon, which, relatively to us, is perfectly equable; or at least, if it be subject to irregularities, they are too minute to be appreciated.

In order to form a precise idea of the phenomenon of the libration, we must consider that the disk of the moon, seen from the centre of the earth, is terminated by the circumference of a great circle of the moon, the plane of which is perpendicular to a line drawn from the earth's centre to that of the moon. The lunar hemisphere is projected on the plane of this circle turned towards the earth; and if the moon did not revolve round her axis, the projection would incessantly present different appearances to us, inas-

Theoretical Astronomy.

much as the radius vector drawn from the centre of the earth by which the plane of projection is determined, would intersect the surface of the moon in a different point, at every new position in her orbit. But in consequence of her rotation, the radius vector is always directed to nearly the same point of the lunar surface, and would be always directed exactly to the same point if the angular velocity of rotation corresponded exactly with the angular velocity in the orbit. But the rotation of the moon is sensibly uniform; while the motion of revolution, being affected by the periodic inequalities, is sometimes slower and sometimes more rapid. The apparent rotation occasioned by the revolution of the moon round the earth is consequently in such cases not exactly counterbalanced by the real rotation, which remains constantly the same. Hence the different points of the lunar globe must appear to turn about her centre, sometimes in one direction, and sometimes in the contrary, and the same appearances be produced as would result from a small oscillation of the moon, in the plane of her orbit, about the radius vector drawn from her centre to the earth. The spots near the eastern or western edge of her disk disappear according as her motion in her orbit is more or less rapid than her mean motion. This is called the *Libration in Longitude.*

Further; the axis of rotation of the moon is not exactly perpendicular to the plane of her orbit. If we suppose the position of this axis fixed, during a revolution of the moon it inclines more or less to the radius vector, so that the angle formed by these two lines is acute during one part of her revolution, and obtuse during another part of it; hence the two poles of rotation and those parts of her surface which are near these poles are alternately visible from the earth. This is the *Libration in Latitude.*

Besides all this, the observer is not placed at the centre of the earth, but at its surface. It is the radius drawn from his eye to the centre of the moon which determines the middle point of her visible hemisphere. But, in consequence of the lunar parallax, it is obvious that this radius must cut the surface of the moon in points sensibly different according to the height of that luminary above the horizon. An observer at the surface of the earth perceives points on the upper part of the moon's disk, at the time of her rising, which could not be seen from the centre. In proportion as the moon acquires a greater elevation, these points approach the border of the disk, and finally disappear, while new ones become visible on the eastern part of the disk, which increase in number as the moon descends towards the horizon; so that in the course of a day she appears to oscillate about her radius vector in the direction of the earth's rotation. This phenomenon constitutes what is called the *Diurnal Libration,* and is evidently the effect of the lunar parallax.

The libration in latitude and the diurnal libration were discovered by Galileo soon after the invention of the telescope. It was Hevelius who discovered the libration in longitude, and explained it by the hypothesis of the equable rotatory motion of the moon combined with her unequal velocity in her orbit.

To the inhabitants of the moon, if such there be, the earth will appear as a species of moon, much larger than the moon appears to us, but visible only to that hemisphere which is turned towards the earth. At those places which are situated near the border of her visible disk, the earth will sometimes rise a few degrees above the horizon; and an inhabitant of the moon placed near the middle of the hemisphere presented to the earth will always see the earth near his zenith, making oscillations of only a few degrees in consequence of the libration. But an inhabitant of the other hemisphere will never see the earth at all; so that while one hemisphere of the moon is constantly enlightened, during her long night, by the light reflected from the earth, the other remains in constant darkness. In regard, therefore, to the distribution of light, one of the lunar hemispheres enjoys very great advantages over the other.

Theoretical Astronomy.

The elements of the rotation of the moon, that is to say, the position of her equator, the place of its nodes, and its inclination to the plane of the ecliptic, are found by the same methods which have been explained for determining the corresponding elements relatively to the sun. The geocentric positions of the spots are observed in the same manner; and in converting them into selenocentric latitudes and longitudes, the same formulæ may be employed, with a slight modification rendered necessary by the inclination of the lunar orbit to the ecliptic. One circumstance, not less remarkable than the coincidence which obtains between the times of rotation and sidereal revolution, is, that the nodes of the lunar equator coincide with those of the moon's orbit, if not exactly, at least so nearly, that the differences are so small as to fall within the probable errors of observation and calculation. All the observations since the time of Hevelius agree in showing that the longitude of the descending node of the equator is very nearly equal to the mean longitude of the ascending node of the orbit; whence it follows that the nodes of the equator have a retrograde motion equal to that of the nodes of the orbit. With regard to the inclination of the lunar equator to the ecliptic, Mayer states it to be 1° 29′, and Lalande 1° 43′. According to the latest computations made from the observations of Bouvard, the mean inclination of the lunar equator to the ecliptic is 1° 28′ 42″. Mr Baily makes it 1° 30′ 10″·8. Since the descending node of the equator coincides with the ascending node of the orbit, it is evident that its plane must be situated between the planes of the ecliptic and orbit, making an angle of about 1° 30′ with the first, and of 3° 39′ with the second.

Suppose three planes to pass through the centre of the moon, one of which represents her equator, the second the mean plane of her orbit, and the third parallel to the ecliptic. It is evident, from what precedes, that these three planes have a common section; that the first falls between the other two, making with them respectively the angles 3° 39′ and 1° 30′. In the space of 6793 days, the time of a revolution of the nodes of the lunar orbit, the poles of the first two planes describe about the pole of the ecliptic, in a direction contrary to the order of the signs, two small circles parallel to the ecliptic, and of which the semidiameters are respectively the arcs 1° 30′ and 5° 9′. Hence the difference between the longitudes of these two poles is constantly 180°, and the three poles are situated on the same great circle, that of the ecliptic being between the two others.

These results, which rank among the most curious discoveries of modern astronomy, were first obtained by Dominic Cassini: they were shown by Lagrange to be necessary consequences of the attraction which the earth exercises on the lunar spheroid.

The positions of the spots on the moon's surface are determined by their distance from the lunar equator, and from a conventional meridian, that is, by their selenocentric latitudes and longitudes, after the manner in which the position of places is determined on the surface of the earth. The first meridian is assumed to be that which passes through the pole of the visible hemisphere when the true place of the moon in her orbit is equal to her mean place; hence the first meridian is always very near the middle of the face which the moon turns towards the earth, never deviating from it farther than by a quantity

equal to the equation of the moon, or her libration in longitude. The rotatory motion being equal to that of revolution, the selenocentric longitude of the first meridian, at any epoch, is found by adding 180° to the mean longitude of the moon; and this gives also the distance of the first meridian from the ascending node of the lunar equator. The position of the equator and first meridian being determined, the co-ordinates of a spot are computed without difficulty; and in this manner catalogues of the spots have been formed, and arranged according to their latitudes and longitudes.

Sect. V.—*Of the Nature and Constitution of the Lunar Substance.*

It has already been observed, that a slight attention to the different phases of the moon is sufficient to prove that she is an opaque spherical body, shining only by virtue of the light which she receives from the sun. The line bounding the visible part of her surface has exactly the form which would be produced by an illuminated hemisphere brought into different positions with respect to the eye; and the circular contour of the obscured portion of the sun during a solar eclipse could only be caused by the interposition of a spherical body. Besides, the parts of her hemisphere turned towards the earth, which the sun's rays do not reach, are in some circumstances sufficiently discernible, and she has then the same circular appearance which she exhibits when at the full.

But if the light which comes to us from the moon is only that which she receives from the sun and reflects back to the earth, how does it happen, it may be asked, that the portion of her disk not directly exposed to the solar rays is distinctly visible for some days after the new moon? This phenomenon was ascribed by the ancients to the native light of the moon, to which, on account of its pale ashy hue, they gave the name of *lumen incinerosum*. The explanation which is now generally given was first suggested by a celebrated painter, Leonard da Vinci. It consists in supposing that a portion of the light which is reflected from the illuminated hemisphere of the earth to the moon undergoes a second reflection at the lunar surface, and is transmitted back to the earth. The ancients were confirmed in their opinion respecting the native light of the moon, by observing that she is not altogether invisible in her eclipses. Plutarch, indeed, ingeniously ascribes her appearance under these circumstances to the light of the stars reflected from the moon; a cause, however, totally inadequate to produce the effect. This phenomenon is now generally ascribed to the scattered beams of the sun bent into the earth's shadow by the refraction of its atmosphere.

The opinion that the moon's light is chiefly, if not wholly, caused by the reflection of the sun's rays at the lunar surface, has prevailed in all ages; and indeed no other explanation seems to have been thought of till it was suggested by Licetus, professor of philosophy at Bologna, as being more probable that the moon possesses a phosphorescent quality, and that the sun's influence is only wanted to occasion the propulsion of the light which lies absorbed in her substance. This idea has been adopted by Professor Leslie, whose arguments in its support are at least extremely plausible and ingenious. So far as the appearances, and the explanation of the phases, are concerned, it is evidently matter of indifference whether we suppose that the solar rays are reflected from the surface of the moon, or that they exert an action in virtue of which the moon emits rays of her own. In either case it is that part of her surface only which is exposed to the impact of the solar rays that sends forth light to the earth.

The principal argument in favour of the phosphorescent nature of the moon is founded on the quantity of light which proceeds from her surface. It is evident that the moon does not act as a polished speculum, and reflect the whole of the incident rays; for in that case, as is known from the laws of *Catoptrics*, she would merely reflect an image of the sun, equally bright, varying in size according to her different positions relatively to the sun and the earth, and increasing till she arrives at her opposition, when her diameter would appear equal to about the 458th part of its real dimensions. Her phases could never be distinguished, and she would only appear to approach to or recede from the earth, in proportion as her diameter increased or diminished. It follows, therefore, that the moon's surface must be irregular, or what is termed a *mat surface*, that is, of such a nature, that from every point of it the rays of light are reflected in all directions indifferently. According to the experiments of Bouguer, a white surface of this sort, for instance paper, or plaster of Paris, reflects only about the 150th part of the rays which fall upon it in a perpendicular direction; and the proportion is less as the angle of incidence becomes more oblique. Making allowance for the irregular surface and obscure spots of the moon, Mr Leslie computes that the solar light which she remits to the earth must be attenuated at least 105 million times; but Bouguer's experiments show that the moon's light is between the 250,000th and 300,000th part of the direct light of the sun, or about 350 times greater than the computed amount of reflected light. If every part of the moon's surface reflected the light in the most perfect manner, it may be shown that only the 210,000th part of the rays which she receives from the sun would be thrown off in the direction of the earth; a quantity not much exceeding that which, according to Bouguer's estimate, we actually receive from her. Mr Leslie states that he found the intensity of the moon's light to approach the 150,000th part of the direct light of the sun; a result which, if admitted, must be entirely decisive of the question; for as the utmost possible quantity of reflected light cannot exceed the 210,000th part, it follows that the excess must be owing to the spontaneous light of the moon. Hence this ingenious philosopher concludes that the body of the moon is a phosphorescent substance, like the *Bolognian Stone*, which possesses the property of shining for some time when carried into a dark room, after having been exposed to the light of the sun. A fact first observed by the celebrated Arago seems to increase the probability of this opinion. All rays reflected from a surface not metallic acquire a peculiar modification, or become *polarized*; but as the rays of the moon are not so modified, it is inferred that they have not undergone a reflection at her surface.

The secondary light of the moon, of which we have already made mention, affords arguments in favour of her native light precisely similar to the above. If the earth reflected, like a mirror, the whole of the incident rays, the illumination produced by the reflection would amount to about a 16,000th part of that which is caused by the sun; but as the sea reflects only about a 55th part of those rays, and the land a still smaller proportion, we may suppose that the reflected light of the earth does not exceed a millionth part of the direct light of the sun. It is extremely doubtful whether a light so greatly attenuated would suffice to render the moon visible. The lucid bow, or silvery thread of light, which, proceeding from the extremities of the lunar crescent, seems to embrace her unenlightened orb, is easily explicable on this hypothesis;

Theoretical Astronomy.

whereas it can hardly be satisfactorily accounted for by ascribing it to the secondary illumination from the earth. "I should rather refer it," says Mr Leslie, "to the spontaneous light which the moon may continue to emit for some time after the phosphorescent substance has been excited by the action of the solar beams. The lunar disk is visible although completely covered by the shadow of the earth: nor can this fact be explained by the inflection of the sun's rays in passing through our atmosphere; for why does the rim appear so brilliant? Any such inflection could only produce a diffuse light, obscurely tinging the boundaries of the lunar orb; and, in this case, the earth, presenting its dark side to the moon, would have no power to heighten the effect by reflection. But even when this reflection is greatest about the time of conjunction, its influence seems extremely feeble. The lucid bounding arc is occasioned by the narrow *lunula*, which, having recently felt the solar impression, still continues to shine; and from its extreme obliquity, glows with concentrated effect." (*Inquiry into the Nature and Propagation of Heat.*)

Fig. 48. Although these arguments go far to support the ancient opinion of the native light of the moon, they are not entirely conclusive; and indeed cannot be easily reconciled with some of the phenomena. If the moon shines in virtue of her native light, rays will be emitted in all directions from every point of her surface; whence, since a visual angle of a given magnitude includes a much larger portion of a spherical surface near the extremities of its apparent disk than towards the centre, and as the number of rays is proportional to the surface from which they proceed, it follows that the intensity of the moon's light ought to be greater near the border than at the centre of her disk. The reason why this is not the case with regard to the sun is, that a greater proportion of the rays are absorbed in passing through a greater extent of the solar atmosphere; but the moon, having no atmosphere, ought to be sensibly most brilliant near the circumference of her orb. The contrary is, however, the case; her light is greatest at the centre, and less intense towards the circumference, exactly as it ought to be on the supposition of its being occasioned by the reflection of the solar rays. With regard to the ingenious argument of Arago, it cannot be held to be conclusive till we become more certainly acquainted with the nature of the lunar substance. The only property which we can safely ascribe to it as yet is *density*: whether in its physical properties it resembles the substances with which we are acquainted, is a question hardly within the bounds of legitimate investigation.

The spots of the moon, affording grounds for conjectures relative to her physical constitution and the nature of her surface, have been observed with great interest since the discovery of the telescope; and as they are of some service in the observation of eclipses, astronomers have been at much pains to determine their selenographic positions. On account of their number, it has been found necessary to distinguish them by particular names. Riccioli designated the most conspicuous of them by the names of astronomers, and other eminent men. Hevelius gave them the names belonging to countries, islands, seas, and regions on the earth, without reference to situation or figure. The nomenclature of Riccioli has, however, been deservedly preferred by Schroeter and others who have particularly observed the phenomena of the lunar surface, and is now universally followed. Mayer gave a catalogue of 89 of the most remarkable of the spots, with their selenographic latitudes and longitudes referred to a first meridian, namely, that which passes through the centre of the moon's apparent disk, perpendicular to the lunar equator, accompanied by an accurate map of her surface. Delineations of the lunar disk have also been given by Hevelius in his *Selenographia*; by Cassini, Russel, Schroeter, Lohrmann, and others. The engraving (fig. 47) which accompanies this article gives a pretty accurate view of the appearance of the moon in her mean libration.

Theoretical Astronomy.

Plate LXXX. Fig. 47.

The following table contains the selenographic positions of some of the principal spots. The sign + indicates a northern, and — a southern latitude.

No.	Riccioli's Names.	Long.	Lat.
1	Zoroaster	West 72°	+ 58°
2	Mercurius	67	+ 40
3	Petavius	64	— 24
4	Langrenus	62	— 8
5	Endymion	60	+ 53
6	Cleomedes	55	+ 26
7	Atlas	48	+ 47
8	Hercules	42	+ 48
9	Censorinus	32	0
10	Fracastorius	32	— 22
11	Possidonius	32	+ 31
12	Theophilus	27	— 12
13	Cyrillus	25	— 13
14	St Catharina	24	— 18
15	Menelaus	15	+ 16
16	Aristoteles	West 15	+ 50
17	Ptolomæus	East 2	— 10
18	Arzachel	3	— 20
19	Archimedes	5	+ 28
20	Tycho	10	— 43
21	Plato	10	+ 52

30	Gassendus	39	— 19
31	Aristarchus	48	+ 24
32	Hevelius	67	— 1
33	Schickardus	68	— 49
34	Grimaldus	East 68	— 5

Great inequalities on the surface of the moon.

That there are prodigious inequalities on the surface of the moon, is proved by looking at her through a telescope at any other time than when she is full; for then there is no regular line bounding the dark and illuminated parts, but the confines of these parts appear as it were toothed and cut with innumerable notches and breaks; and even in the dark part, near the borders of the enlightened surface, there are seen some small spaces enlightened by the sun's beams. Upon the fourth day after new moon there may be perceived some shining points, like rocks or small islands, within the dark body of the moon; but not far from the confines of light and darkness there are observed other little spaces which join to the enlightened surface, but run out into the dark side, which by degrees change their figure, till at last they come wholly within the illuminated face, and have no dark parts round them at all. Afterwards many more shining spaces are observed to arise by degrees, and to appear within the dark side of the moon, which, before they drew near to the illumined portion of the disk, were invisible, being totally immersed in the shadow. The contrary is observed in the decreasing phases, where the lucid spaces which

Theoretical Astronomy.

joined the illuminated surface recede gradually from it, and remain for some time visible after they are quite separated from the confines of light and darkness. Now it is impossible that this should be the case, unless these shining points were higher than the rest of the surface, so that the rays of the sun may illumine their summits before they reach their bases. Portions of considerable extent are also perceived on the lunar surface, which are never brilliant like the other parts, but remain constantly obscure. These are supposed to be deep valleys or cavities: they were formerly supposed to be seas, but, for reasons about to be given, this idea has been abandoned.

These phenomena render it certain that the surface of the moon is covered with mountains of a great height, with rocks or masses of unknown matter, but possessing the property of reflecting the sun's light. The height of the lunar mountains may be determined in the following manner.

Fig. 48.

Let ABO (fig. 48) be the illuminated hemisphere of the moon, SO the tangential solar ray, and consequently O one of the points of the circle which separates the enlightened from the obscure hemisphere. All the part OD will be in darkness; but if this part contain a mountain aM so elevated that its summit M reaches the solar ray SO, the point M will be enlightened. Now, if the line OM can be determined by observation, it will be easy to deduce the arc Oa, and thence the height of the mountain aM, in terms of the moon's radius. Let E be the place of an observer on the earth; draw the lines EM, EO, EC (C being the centre of the lunar orb), and Om perpendicular to EM. The distance of the moon from the earth being known, we have the distance **EO**: the angle OEm is measured by the micrometer; therefore Om, which is the projected distance of OM, is a given quantity. Now $\mathrm{OM} = \frac{\mathrm{O}m}{\cos.\ \mathrm{MO}m}$; and since OE$m$ is a very small angle, EOm may be considered a right angle, consequently $\mathrm{MO}m = \mathrm{MOE} - 90°$; therefore $\mathrm{OM} = \frac{\mathrm{O}m}{\cos.\ (\mathrm{MOE} - 90°)} = \frac{\mathrm{O}m}{\sin.\ \mathrm{MOE}} = \frac{\mathrm{O}m}{\sin.\ \mathrm{EOS}}$. that is, the distance between the summit of the mountain and the illuminated part of the moon's disk is equal to the projected distance measured by the micrometer, divided by the sine of the moon's elongation from the sun. Suppose this distance $\mathrm{OM} = n \times \mathrm{CO}$; we shall then have $\mathrm{CM} = \mathrm{CO}\sqrt{1 + n^2}$, and the height of the mountain $a\mathrm{M} = \mathrm{CO}(\sqrt{1 + n^2} - 1) = \frac{n^2}{2}\ \mathrm{CO}$ (neglecting in the development of the radical the powers of n which are higher than the square). According to the observations of Hevelius, the greatest value of n is $\frac{1}{15}$, which gives the height of the mountain equal to $\frac{1}{338}$ of the semidiameter of the moon. Schroeter, who estimated the heights of the lunar mountains by measuring the projections of their shadows at the time the sun was near their horizon, makes it in some cases $\frac{1}{214}$. The highest mountains on the earth do not reach an elevation greater than $\frac{1}{1000}$ of the terrestrial radius; the lunar mountains, therefore, in proportion to the diameters of the earth and moon, are nearly five times higher than those of our globe. Their absolute height is above five English miles. It is easy to see that these determinations are susceptible of very little accuracy.

Not only is the moon's surface rendered irregular by high and precipitous mountains, but numerous cavities appear in every part of her surface, some of which, according to Schroeter, are upwards of four English miles in depth, and forty in circumference at the orifice. An insulated mountain is frequently observed to rise in the centre of these enormous pits or caverns; and they are surrounded by high annular ridges, the masses of which would exactly fill the inclosed cavities. From this circumstance, it is probable that the elevations and hollows which abound on the surface of the moon have been produced by volcanic eruptions. Herschel imagined that he even observed volcanoes in activity. At the time of the new moon he perceived on different parts of her obscure disk three luminous points, resembling pieces of burning charcoal, covered with a thin coat of white ashes, one of which, by a comparison with the third satellite of Jupiter, appeared to be upwards of three miles in diameter. Their brilliancy continued during several days, undergoing variations altogether independent of the increase of the moon's apparent magnitude, and at the end of that time they appeared to become extinct.

Theoretical Astronomy

The existence of a lunar atmosphere has been a fertile subject of controversy among astronomers. It has been urged that, as the brightness of the moon is sensibly equal at all times when she is not obscured by clouds in the terrestrial atmosphere, she cannot be surrounded by an atmosphere similar to that of our earth, so variable in its density, and so liable to be obscured by clouds and vapours. The assumption of an equable brightness in the appearance of the moon has not, however, been allowed to pass uncontroverted. Hevelius relates that he has several times found in skies perfectly clear, when even stars of the sixth and seventh magnitude were visible, that, at the same altitude of the moon, at the same elongation from the earth, and with the same telescope, the moon and her maculæ do not appear equally lucid and clear at all times, but are much brighter and more distinct at some times than at others. Several other observers have noticed that the moon is not always equally conspicuous during total eclipses; a fact which is held to be indicative of accidental variations in the state of the lunar atmosphere.

Lunar atmosphere.

Another objection against the existence of a lunar atmosphere is derived from the circumstance that, if it existed, its influence would be perceptible in the occultations of the planets, or fixed stars, by the moon. When the moon approaches so near to a star that part of her atmosphere (supposing she has one) is interposed between the star and the eye of the observer, the star, it is contended, ought to suffer a change in its colour in consequence of the absorption of some of its light in traversing the denser parts of the moon's atmosphere. But when we consider that the region of the vapours and clouds in the terrestrial atmosphere does not exceed the height of four miles, or the 1980th part of the earth's diameter, and that consequently the obscure part of the lunar atmosphere, supposing it to be similarly constituted, would not subtend an angle of one second (the mean apparent diameter of the moon being 1889 seconds), and that this space is passed over by the moon in less than two seconds of time, it will scarcely be expected that observation will be able to decide whether the supposed obscuration takes place or not. Some observers have, however, remarked instances of stars, when about to be occulted, presenting an evident diminution of light. (See a Paper by Mr Ramage of Aberdeen, in the 2d vol. of the *Memoirs of the Astronomical Society*.)

The existence of a lunar atmosphere cannot increase or diminish the apparent diameter of the moon, because its effect on the rays of light when they enter it will be exactly counteracted at the time of their emergence. It might seem, therefore, that in order to determine whether the light of a star or planet is inflected when it passes very near the

Theoretical Astronomy.

border of the lunar disk, it would be sufficient to compare the observed duration of the occultations of the stars, or eclipses of the sun, with the time, calculated from the theory of the moon's motion, which she consumes in passing through a space equal to her apparent diameter. But if, as is generally supposed, a certain irradiation is produced around luminous objects, by which their image is dilated, the apparent diameter of the moon will thereby be augmented when she is projected on the dark sky. On the contrary, when the disk of the moon is projected on that of the sun in annular eclipses, the irradiation, by dilating the luminous ring which seems to surround the moon, will cause her apparent diameter to appear smaller than it actually is. On this account it becomes very difficult to ascertain by direct measurement the amount of the inflection of light at the border of the lunar disk, or even to be certain of its existence. An indirect method of arriving at the desired object was, however, imagined by Dionis du Sejour, who regarded the irradiation and inflection as two unknown quantities to be determined simultaneously from the observations of the phases of eclipses, upon which their effects are different. The observations best adapted for this purpose are those of the magnitude of the luminous crescent, and its successive increase in annular eclipses. Du Sejour calculated with great care the annular eclipse of the sun which took place in the year 1764, and was visible over all Europe; and which, by reason of the extent and variety of its phases, presented a great many points of comparison. He particularly employed the observations made in different places of the instants of the formation and rupture of the ring. He likewise confirmed these observations by measurements made by Mr Short, at London, of the distance between the horns of the crescent at divers instants. It resulted, from the comparison of an immense number of observations, that the measurements could not be reconciled without supposing an irradiation of 3″ on the semidiameter of the sun, and an inflection of nearly the same amount round the disk of the moon, produced by her atmosphere. According to this result, the horizontal refraction at the surface of the moon amounts to 1″·5. The mean horizontal refraction observed at the surface of the earth is 0°·585, and consequently about 1400 times greater than that at the moon. Hence, supposing the moon's atmosphere of the same nature as that of the earth, its density must be 1400 times less, and consequently rarer than the most perfect vacuum which can be produced by the best pneumatic machines.

The existence of a lunar atmosphere, though of small extent, is indicated with considerable probability by the observations of Schroeter, who perceived that some ranges of lunar mountains, when in the dark hemisphere, are illuminated more feebly in proportion as they recede from the boundary of light and darkness; an effect which would be produced by the partial absorption of the rays of light which pass near the moon's surface. He also remarked the same circumstance with regard to the cusps, and perceived other indications of an atmosphere in some changes of tint, which induced him to think that a twilight might be discernible towards the cusps. With a view to prove the accuracy of this conjecture, he examined the moon with great care under the most favourable circumstances, and at length descried a faint glimmering which he took to be crepuscular light, extending from the cusps into the dark body of the moon. Its greatest breadth was 2″; and it extended 1′ 20″ from the cusps, along the circumference of the lunar disk. From these data he computed that the height of the lunar atmosphere, to the limit where it ceases to inflect the rays of light or diminish the brightness of a star, does not exceed 5742 English feet. A ring of this breadth, at the distance of the moon, will subtend an angle of only 0″·94; hence the almost imperceptible influence of the lunar atmosphere.

Some observations, related by Mr Ramage of Aberdeen, in a memoir already alluded to, of occultations of Jupiter and his satellites, with an excellent reflecting instrument, also tend to confirm the existence of a small lunar atmosphere. On the approach of the satellites no diminution of their light was perceptible. On coming into contact with the moon's limb they did not disappear instantly, like fixed stars, but formed an indentation or notch in the limb, as if imbedded in it, but at the same time *separated from it by a fine line of light.* The indentation continued visible till about half their diameters were immersed, when it disappeared. (*Memoirs of the Astronomical Society of London*, vol. ii. p. 87.)

The dark spots on the moon's surface were formerly supposed to be water; but as elevations and cavities are distinctly perceptible in them, that hypothesis is evidently erroneous. Besides, the extreme tenuity of her atmosphere is inconsistent with the existence of water at her surface. It is only by the weight of the terrestrial atmosphere that the liquids at the surface of the earth are prevented from being dissipated in vapours. If the present atmosphere were removed, every liquid would continue to be dissipated in this manner till a new atmosphere was formed, to which each would contribute in proportion to its elastic force; and the evaporation would only cease when the tension of the vapour of each liquid was equal to its elastic force in a vacuum at the same temperature. But if the vapours were removed as they arose, by any absorbing cause, the evaporation would continue till the liquids entirely disappeared. Now we may suppose this to have been the case with respect to the moon, and that at one time she may have had an atmosphere, which the attractive force of the earth, aided by some accidental circumstance, may have swept away and united with our own. (Biot, *Astr. Phys.* tome ii. p. 413.)

Under these circumstances it is evident, that no animal, similarly constituted to those which inhabit the earth, could respire at the surface of the moon.[1] Every thing there appears solid, desolate, and unfit for the production and support of organized substances; and the excessive cold which certainly prevails must be sufficient to destroy every source of animal or vegetable life. May it not then be supposed that the moon is a planet which has not yet reached a state of maturity—a maturity to be prepared by successive volcanic eruptions; or that, having fulfilled its destiny, it is now in a state of decay?

On the subject of this section, see Hevelius, *Selenographia;* Schroeter, *Selenotopographische Fragmente;* Hooke's *Micrographia*, 1665; Lemonnier, *Selenographie;* Mayer, *Cosmographische Nachrichten*, 1748; Boscovich, *De Lunæ Atmosphæra*, 1753; Dunn, *Phil. Trans.*, 1762; Herschel, *Phil. Trans.*, 1780 and 1787, p. 229; Ferguson's *Astronomy*, by Brewster; Biot, *Astronomie*, tome ii. p. 413; Schubert, *Traité d'Astronomie Théorique*, tome ii. p. 364.

[1] It has always been a favourite opinion with mankind, that the celestial bodies, resembling the earth in some respects, are also, like it, peopled with rational beings. The author of the verses attributed to Orpheus ascribes to the moon many mountains, and cities, and palaces:

ἡ πολλ' ουρε' εχει, πολλα αστεα, πολλα μελαθρα.

Sect. VI.—*Of Eclipses and Occultations.*

In describing these interesting phenomena, we will first consider the eclipses of the moon, which, for any given place on the earth, are much more frequent than those of the sun, and, by reason of certain circumstances about to be explained, can also be computed with much greater facility.

1.—*Eclipses of the Moon.*

The earth being an opaque, round body, much smaller than the sun, must project behind it in space a conical shadow, limited by straight lines drawn from the extremities of the sun's disk to touch the surface of the earth. When the moon enters this shadow, and a portion of her disk is still enlightened by the sun, the enlightened part will necessarily have the form of a luminous crescent, the concavity of which is turned to the conical shadow of the earth; and this appearance will likewise be exhibited when the moon begins to emerge from the shadow. As she approaches towards the shadow, her light is not suddenly eclipsed, but passes insensibly through all the successive gradations of obscurity, till the darkness attains its greatest intensity. The reason of this will be easily comprehended by considering that when an opaque body is placed between an object and the sun, so as to conceal only a part of his disk, the object is then less enlightened than when none of the solar rays are intercepted; and this in proportion as more or less of the sun is concealed. Between full illumination and total obscurity there are consequently intermediate tints and gradations of light, which are denominated the *Penumbra*, in contradistinction to the *Umbra* which covers those places to which the sun's rays are completely intercepted. Let S and E (fig. 49) be the centres of the sun and earth, and ABB′A′ any plane whatever passing through the axis SE, in which, let AB, A′B′ be tangents to the sun and earth on opposite sides of the axis SE; these tangents will meet the prolongation of the axis in a point C. Let also AB′, A′B touch the sun and earth on opposite sides of SE, and let C′ be their intersection. If we now suppose the plane to turn round the axis SC, a conical shadow or umbra, of which the apex is C, will be formed behind BB′; and if the moon is situated within any part of the cone BCB′, no light whatever can fall on her. As soon as the moon emerges from this cone, a part at least of the sun's rays will fall upon her, and she will be in the penumbra. If situated, for example, at M, and MN be drawn to touch the earth and meet the solar disk in N, then the part of that disk between A and N will be visible at M. The extent of the penumbra is therefore determined by the angle DBC. When M is situated in the straight line BD, the whole of the sun's disk is visible; when M is in BC the sun entirely vanishes, and his visible portion diminishes from the instant M passes BD till it reaches BC. The intensity of the penumbra, therefore, goes on increasing from the first of these limits to the second, where it is confounded with the total darkness. This explains the progressive obscuration of the moon's disk in her eclipses.

If we now attempt to determine the circumstances under which an eclipse of the moon can take place, it is obviously necessary to inquire, in the first place, into the length of the conical shadow BCB′; for an eclipse can only happen on the supposition of its extending beyond the orbit of the moon. For this purpose let EF (fig. 50) be drawn parallel to AB, and meeting SA in F. We have then sin.

Plate LXXXIII. Fig. 50.

$$\text{ECB} = \text{sin. SEF} = \frac{\text{SF}}{\text{SE}} = \frac{\text{SA} - \text{EB}}{\text{SE}} = \text{sin. R} - \text{sin. } p,$$

R being the apparent semidiameter of the sun, and p his horizontal parallax. By reason of the smallness of these angles the arcs may be substituted for the sines; hence the angle ECB $= \text{R} - p$. But $\text{CE} = \frac{\text{EB}}{\text{sin. ECB}}$, therefore making EB, the radius of the earth, $= a$, $\text{CE} = \frac{a}{\text{sin.}(\text{R} - p)}$.

From this expression it is evident that the value of CE depends on the horizontal parallax, and therefore varies with the sun's distance from the earth. On calculating, by means of the values of R, a, and p, given in the preceding sections, the values of CE at the perigean, mean, and apogean distances, the following results will be obtained:—

	Lengths of CE.
Sun in perigee	212·896 terrestrial radii.
at mean distance	216·531
in apogee	220·238

Now the greatest distance of the moon from the earth is less than 64 terrestrial radii (sect. ii.), consequently the shadow of the earth is projected into space between three and four times farther than the distance of the moon. Hence it appears, that if the moon moved in the ecliptic she would traverse the earth's shadow and be eclipsed every revolution. On account of the inclination of her orbit to that plane, the eclipses can only happen when she is in or near her nodes. The greatest distances from the nodes at which they can take place are called the *Lunar Ecliptic Limits*.

In order to determine these limits, it is necessary first of all to know the apparent diameter of a section of the earth's shadow, at the place where it is traversed by the orbit of the moon. Let $l\text{M}l'$ (fig. 50) be a part of the moon's orbit, intersecting the lines AC and A′C in m and m'; then mm' is the geocentric diameter of the shadow, the half of which is measured by the angle mEC. Now the angle mEC is the difference between the angles EmA and ECA, the first of which, namely, EmA, is the apparent semidiameter of the earth seen from the moon, or, in other words, the moon's horizontal parallax. Let this angle, therefore, be denoted by P. It has already been shown that ECA $= \text{R} - p$; consequently we have mEC $= \text{P} + p - \text{R}$ in all cases; that is to say, *the semidiameter of the shadow is equal to the sum of the horizontal parallaxes of the sun and moon, diminished by the apparent semidiameter of the sun.* On calculating the amount of this expression from the values of P and p given above, the following table will be obtained, exhibiting the magnitude of the apparent diameters of the earth's shadow for different distances of the sun and moon.

		Apparent diameters of earth's shadow.
Sun in perigee,	☽ in apogee	1° 15′ 24″·30
	at mean distance	1 23 2 ·31
	in perigee	1 30 40 ·31
Sun at mean distance,	☽ in apogee	1 15 56 ·86
	at mean distance	1 23 34 ·87
	in perigee	1 31 12 ·87
Sun in apogee,	☽ in apogee	1 16 28 ·29
	at mean distance	1 24 6 ·30
	in perigee	1 31 44 ·30

The greatest apparent diameter of the moon being only 33′ 31″·07, which is about a third part of the diameter of the earth's shadow, it follows that the moon may not only be completely enveloped in the shadow, but, since she passes over a space nearly equal to her own breadth in an hour, that she may continue to be totally eclipsed during a space of about two hours.

The above determination refers only to the umbra or cone of total darkness; but the diameter of the penumbra is obtained in a manner exactly similar. In the same

Theoretical Astronomy.

diagram the semidiameter of the penumbra is measured by the visual angle lEC; but lEC = ElC′ + EC′l, and EC′l = EC′l′ = C′EA + C′AE; therefore lEC = ElC′ + C′EA + C′AE; or, retaining the same denominations as above, lEC = P + p + R. Hence, *the semidiameter of the penumbra is equal to the horizontal parallaxes of the moon and sun, augmented by the apparent semidiameter of the sun.*

All the different numerical values of the semidiameter of the penumbra corresponding to particular positions of the sun and moon may be computed exactly in the same manner as in the case of the umbra.

The two expressions for the semidiameters of the umbra and penumbra, viz. P + p — R, and P + p + R, give immediately the distance of the moon's centre from the axis of the cone when her disk comes into contact with the shadow. Representing the apparent semidiameter of the moon by r, her disk will just touch the umbra when the distance of her centre from the axis SE is equal to P + p — R + r; and it will touch the penumbra when the distance is P + p + R + r. But on account of the very feeble obscurity of the penumbra towards its extreme border, it is impossible to observe with any degree of precision the time at which the moon enters it. In computing the ecliptic limits, therefore, it is only necessary to have regard to the umbra.

In the table given above, the extreme values of P + p — R, the apparent semidiameter of the earth's shadow, are ½ (1° 15′ 24″·30) = 37′ 42″·15, and ½ (1° 31′ 44″·30) = 45′ 52″·15; and the least and greatest values of r, the apparent semidiameter of the moon, are respectively 14′ 45″ and 16′ 45″ (sect. ii.); therefore the least distance of the moon's centre from the axis of the shadow at the time of her immergence or emergence is 37′ 42″·15 + 14′ 45″ = 52′ 27″·15, and the greatest 45′ 52″·15 + 16′ 45″ = 62′ 37″·15. The first is the limit within which an eclipse must necessarily happen; the last that beyond which it cannot happen.

It is now easy to ascertain the limits of the moon's distance from her node, within which the eclipses take place. Let NC (fig. 51) be a portion of the ecliptic, NM part of the moon's orbit, N its node, C the centre of a section of the earth's shadow, M the centre of the moon; the verge of the lunar disk touching, but not penetrating, the shadow at a. It is evident that, if the moon be at a greater distance than CM from NC, there can be no eclipse. The greatest value of CM, as we have just seen, is 62′ 37″·15, from which the corresponding ecliptic limit NC is easily computed by means of the formula

sin. CM = sin. NC × sin. CNM.

Supposing the angle CNM, that is, the inclination of the moon's orbit to the ecliptic, to be 5°, which is its minimum value, the value of NC is found from the logarithmic tables to be 12° 2′ nearly. Hence an eclipse of the moon can only happen when she is within about 12° 2′ of her node. Under the most favourable circumstances, however, the limits may extend to 13° 21′. A lunar eclipse will certainly take place if the moon's distance from her node, at the time of her mean opposition, is not greater than 7° 4′.

When the moon's disk only comes into contact with the shadow, as in fig. 51, the phenomenon is called an *appulse;* when the disk only enters into the shadow in part, the eclipse is said to be *partial;* it is called *total* if the moon entirely disappears, and *central* when her centre coincides with the axis of the cone, or if at the time of the eclipse the moon is exactly in her node.

In the preceding determinations the shadow has been supposed to be conical, whereas, on account of the compression of the earth at the poles, it is not exactly a cone, but a conoid on an elliptic base; and it varies at every instant by reason of the earth's rotation. To determine rigorously the figure of the cone at every instant, and the diameter of its section where the moon enters and leaves it, would require calculations of great complication and prolixity. Such precision is, however, unnecessary; and indeed it is impossible to attain to absolute accuracy so long as the figure of the earth is not exactly known. It is usual and natural to employ the largest diameter which the shadow can have at the distance of the moon.

Theoretical Astronomy.

It has also been supposed that the shadow is terminated by tangents to the sun and the earth; that is to say, that all the rays of light which are not obstructed by the globe of the earth pass in straight lines from the sun to the moon. But the earth being surrounded by an atmosphere which near the surface exerts a powerful action on the solar rays, it is to be presumed that those rays which, if unobstructed, would glance by the surface of the earth, are absorbed by the lower strata of the atmosphere. The effect of this will be to enlarge the diameter of the shadow; and the requisite correction may be regarded as an augmentation of the earth's radius, by adding to it a part of the atmosphere; or, which amounts to the same thing, an augmentation of the lunar parallax. Now, it is found by experience that such a correction is necessary; and, according to Mayer, the lunar parallax must be augmented by a 60th part in order to satisfy the observations.

Another effect of the action of the earth's atmosphere on the solar rays is to render the moon dimly visible even when she is totally eclipsed,—a circumstance to which allusion was made in the preceding section. Let the circle f g h i (fig. 52) concentric to the earth include that part of the atmosphere which is sufficiently dense to produce a sensible refraction of the rays of light. All those rays which do not fall within that circle, such as Wfw, Viv, proceed in their direct course without suffering any refraction; but those which enter the atmosphere between f and k, and between i and l, on opposite sides of the earth, are gradually more bent inward as they go through a greater portion of the atmosphere, until the rays Wk and Vl, touching the earth at m and n, are bent so much as to meet at q, a little short of the moon; and therefore the dark shadow of the earth is contained in the space $mopqm$, where none of the sun's rays can enter; all the rest, R, R, being mixed by the scattered rays which are refracted as above, is in some measure enlightened by them; and some of those rays falling on the moon, give her the colour of tarnished copper, or of iron almost red-hot; so that if the earth had no atmosphere, the moon would be as invisible in total eclipses as she is when new. If the moon were so near the earth as to go into its dark shadow, suppose about p or q, she would be invisible during her stay in it, but visible before and after in the fainter shadow R R.

After having pointed out the general phenomena of the lunar eclipses, and the limits within which they take place, it only remains to show in what manner the time of their commencement, end, and duration, and also their magnitude, may be determined by computation.

Let the line NE (fig. 53) represent the ecliptic, NO the orbit of the moon, C the centre of the terrestrial shadow, and M the centre of the moon at the instant of the opposition; then CM will be the circle of latitude on which the opposition takes place. The centre of the shadow C being always in opposition with the sun, moves along the ecliptic from west to east, or from N towards E, with the same velocity as the sun. The moon also, at the same time, moves in her orbit from west to east, or from N towards O. Now the velocities of these two motions are given by the astronomical tables, and the question is to determine the instant of time at which the circles

Plate LXXXIX Fig. 53.

Theoretical Astronomy.

representing sections of the moon and the earth's shadow meet each other either before or after the opposition.

At the time of an eclipse the apparent distance of the centre of the shadow from the moon is very small, consequently CM, and also the differences of the respective longitudes and latitudes of C and M, may be regarded as straight lines. During the short interval between the commencement and end of an eclipse, the motion of the sun, and consequently that of the centre of the shadow, may likewise be regarded as uniform. By these suppositions, sufficiently accurate for our present purpose, the problem is considerably simplified.

Suppose now that C′ and M′ are two simultaneous positions of the shadow and moon at any instant before or after the opposition. Let M′P be perpendicular, and MQ parallel, to NE. The velocities of the moon and terrestrial shadow being known from the tables, the lines C′P and QM′, which represent the motions of the centre of the moon relatively to that of the shadow in longitude and latitude, are known also; whence C′P and PM′ are given, and consequently C′M′ the distance of the centres. Let us assume

λ = CM or ☽'s latitude when in opposition,
s = ☉'s motion in longitude,
m = ☽'s horary motion in longitude,
n = ☽'s motion in latitude,
t = time from M to M′,
c = C′M′ the distance of the centres.

Now, since we suppose that CP and QM′ are the ☽'s motion in longitude and latitude respectively in the time t, it is evident that $CP = mt$, and $QM' = nt$. But CC′ is the sun's motion, or the motion of the terrestrial shadow in longitude during the same time; therefore $CC' = st$. We have then $C'P = mt - st$, and $PM' = \lambda + nt$; consequently

$$c^2 = (mt - st)^2 + (\lambda + nt)^2.$$

In this quadratic equation, if t is regarded as the unknown quantity, the only arbitrary quantity contained in it will be c, the distance of the centres, the others being all determined from the tables. On assigning, therefore, any arbitrary value to c, the resolution of the equation will give the corresponding value of t, and consequently the circumstances or different *phases* of the eclipse which we may wish to determine.

On arranging the terms of the above equation so as to obtain the resolution relatively to t, we have

$$[(m-s)^2 + n^2]\, t^2 + 2\lambda\, nt = c^2 - \lambda^2,$$

which may be still simplified by introducing an auxiliary angle θ, such that $\tan.\ \theta = \frac{n}{m-s}$; for by this substitution there will result

$$n^2 t^2 + 2\lambda n \sin.^2\theta \,.\, t = (c^2 - \lambda^2)\sin.^2\theta,$$

which gives the two following values of t:

$$t = \frac{1}{n}\left(-\lambda \sin.^2\theta \pm \sin.\theta \sqrt{c^2 - \lambda^2 \cos.^2\theta}\right).$$

The first of these denotes the time at which the moon enters, and the second that at which she quits, the umbra or penumbra.

The time at which the different phases of the eclipse happen, are calculated directly from this equation. If, for example, we wish to determine the time at which the moon's disk begins to enter the shadow, we make $c = P + p - R + r$ (neglecting the small augmentation of the shadow occasioned by the refraction of the atmosphere). In the case of the penumbra we must take $c = P + p + R + r$; and it is evident that, if in either case λ is of such a magnitude that c is less than $\lambda \cos.\theta$, the value of t will be impossible; in other words, no eclipse can take place.

If we suppose $P + p - R + r = \lambda \cos.\theta$, the two values of t will be equal, and the duration of the phase will only be for an instant, as in the case of the appulse, in which the moon's limb just touches the shadow without entering it. In general, the portion of the diameter of the eclipsed part is $P + p - R + r - \lambda \cos.\theta$; and consequently the diameter of the part not eclipsed is equal to the diameter of the moon, or $2r$, minus this quantity, that is, equal to $\lambda \cos.\theta - P - p + R + r$. When this expression is equal to nothing the eclipse is just a total one; when negative, the upper boundary of the moon's limb will be under the upper boundary of the section of the shadow, and the total eclipse will continue for some time.

The instant at which the middle of the eclipse happens will evidently be that at which the two values of t are equal, or when the radical disappears, that is, when $c = \lambda \cos.\theta$. In this case $t = -\frac{1}{n}\lambda \sin.^2\theta$, and the instant is called that of the *greatest phase*. It is usual to express the quantity of the eclipse in digits, or twelfths of the lunar diameter; so that the eclipsed part is represented by $\frac{12}{2r}(P + p - R + r - \lambda \cos.\theta)$. Thus, taking the moon's apparent diameter at 33′ 18″, and supposing the eclipsed part to be 24′ 52″, this part expressed in digits will be $\frac{24'\ 52''}{33'\ 18''} \times 12 = 8{\cdot}96$ digits.

The obscurity of the penumbra renders observations of the commencement and termination of the lunar eclipses extremely uncertain. To obviate in some degree this inconvenience, care is taken to observe as accurately as possible the instants at which the shadow arrives at or passes different known spots on the moon's disk; so that the same eclipse offers in fact a great number of different observations, the mean of which may be regarded as more certain than any individual one. But after all the precautions that can be taken, the eclipses of the moon are far from affording results equally precise and certain as those of the sun. They were formerly of much greater importance than they are in the present state of astronomy; for the ancients had no other means of determining the geographical longitudes of places on the earth. In fact, as the eclipse is occasioned by the moon's being deprived of her light, the different phases of the eclipse happen at exactly the same physical instant of time to all observers to whom the moon is visible. The difference of the time reckoned by two observers at the instant of the phenomenon will therefore give the difference of the horary angles, or of their meridians; but supposing each to have made a mistake of 4 minutes of time in an opposite sense (and the ancients could scarcely guarantee a greater degree of accuracy), the resulting error in the difference of longitude would amount to 2°. The geographical tables of Ptolemy contain errors of still greater magnitude.

2.—*Eclipses of the Sun.*

The eclipses of the sun are caused by the interposition of the moon between the sun and the earth, and their general phenomena may be explained in the same manner as those of the moon. When the conical shadow which the moon projects behind her in space reaches the earth, those points of the earth's surface on which it falls are completely deprived of the light of the sun, and involved in total darkness. Those parts of the earth which are covered by the penumbra are only partially deprived of the sun's light, because the moon does not conceal the whole, but only a part of the solar disk.

Theoretical Astronomy.

In order to appreciate the different circumstances of a solar eclipse, the procedure to be adopted is in many respects the same as that which has been explained in regard to the eclipses of the moon. The length of the moon's shadow, the first object of inquiry, is found exactly in the same manner as that of the earth; and it is only necessary to substitute in the formulæ already given the values of the apparent diameter and parallax of the sun which they would have at the surface of the moon. Now, these values are easily found, for the diameter of the sun as seen from the moon is equal to his diameter as seen from the earth, increased in the ratio of the distances of the moon and earth from the sun. In the same manner the parallax of the sun relatively to the moon is equal to his parallax relatively to the earth, augmented in the ratio of the distances, and diminished in the ratio of the diameters, of the moon and earth. Thus, let D represent the distance of the earth from the sun, d the moon's distance from the sun, m the moon's true semidiameter, and a the semidiameter of the earth; the sun's apparent semidiameter as seen from the moon will be $R \cdot \frac{D}{d}$ (R being his apparent semidiameter as seen from the earth), and his horizontal parallax will be $p \cdot \frac{D}{d} \cdot \frac{m}{a}$. The formula then which expresses the length of the terrestrial shadow CE (fig. 50), namely, $\frac{a}{\text{sin. } (R - p)}$, adapted to the case of the moon, becomes $\frac{m}{\text{sin.} \left\{ \left(R - p \cdot \frac{m}{a} \right) \frac{D}{d} \right\}}$, and expresses the distance between the centre of the moon and the apex of her shadow. By means of this formula the following results, which refer to the extreme cases in which the length of the shadow is a maximum and minimum comparatively with the moon's distance from the earth, may be computed.

		Length of shadow.	Moon's distance.
Sun in apogee,	Moon in perigee,	59·730	55·902
Sun in perigee,	Moon in apogee,	57·760	63·862

In the first case the shadow of the moon will reach beyond the centre of the earth; in the second it will not reach even to the surface. It follows, therefore, that even if the orbit of the moon coincided with the ecliptic, she would not produce a total obscurity every time she comes between the sun and the earth. At her greatest distances, where the shadow does not reach the earth, the effect of her interposition would be to conceal only a part of the sun's disk.

By introducing into the other formulæ modifications similar to the above, we shall find the apparent diameter of the shadow and the solar ecliptic limits. The apparent semidiameter of the earth's shadow has been shown to be equal to $P + p - R$; consequently the semidiameter of the lunar shadow at the distance of the earth, as seen by an observer placed on the moon, is equal to the parallax of the earth, plus the parallax of the sun relatively to the moon, minus the apparent semidiameter of the sun seen from the moon. The parallax of the earth means simply the apparent semidiameter of the moon seen from the earth; and if we neglect the parallax of the sun, which cannot influence the result to the extent of half a second, we shall have the following theorem: *The semidiameter of the lunar shadow is equal to the excess of the apparent semidiameter of the moon above the apparent semidiameter of the sun.* Hence, denoting the moon's apparent semidiameter by r, the semidiameter of the lunar shadow will be expressed by $r - R \cdot \frac{D}{d}$; or, taking into account the sun's parallax, $r + p \cdot \frac{m}{a} \cdot \frac{D}{d} - R \cdot \frac{D}{d}$. The ratio of the distances $\frac{D}{d}$, in this and the preceding formula, may be expressed in terms of the parallaxes; for since $p = \frac{a}{D}$, and $P = \frac{a}{D - d}$, therefore $\frac{D}{d} = \frac{P}{P - p}$. Since also $\frac{m}{a} = \frac{r}{P}$, according to the nature of parallax, we have likewise $r + p \cdot \frac{m}{a} \cdot \frac{D}{d} = \frac{r P}{P - p}$; therefore, by substituting these values, the expression for the semidiameter of the lunar shadow becomes

$$(r - R) \cdot \frac{P}{P - p}.$$

If to the apparent semidiameter of the shadow at the point where it is touched by the earth, we add the apparent semidiameter of the earth as seen from the moon, that is to say, the moon's horizontal parallax (P), the distance between the centres of the moon's shadow and of the earth will be

$$P + (r - R) \frac{P}{P - p},$$

from which expression the solar ecliptic limits may be readily computed. The result of the computation is, that a solar eclipse may take place if the moon's distance from her node, at the time of her mean conjunction with the sun, does not exceed 19° 44′. If her distance from the node is less than 13° 33′, the sun will certainly be eclipsed in some part of the world.

The solar eclipses present a great variety of appearances, depending on the relative positions of the sun, the moon, and the spectator. If the apparent diameter of the moon happens to surpass that of the sun, the eclipse will be *total*; but if the moon's diameter be the smaller, the observer will see a luminous ring, formed by that part of the sun's disk which exceeds that of the moon, and the eclipse will in that case be *annular*. If the centre of the moon is not in the same straight line which joins the observer and the centre of the sun, the eclipse can only be *partial*, as the moon can only conceal a *part* of the sun's disk. When the moon merely touches without penetrating the solar disk, the phenomenon is called an *appulse*; and the eclipse is *central* if the observer is placed at the centre of the shadow, on the straight line joining the centres of the sun and moon.

When the change happens within 17 degrees of the node, and the moon is at her mean distance from the earth, the point of her shadow just touches the earth, and she eclipses the sun totally to that small spot whereon her shadow falls; but the darkness is not of a moment's continuance.

The moon's apparent diameter, when largest, exceeds the sun's, when least, only two minutes of a degree; so that in the greatest eclipse of the sun that can happen at any time and place, the total darkness continues no longer than whilst the moon passes over two minutes in her orbit, that is, about 3 minutes and 56 seconds of an hour.

Extent of the moon's shadow and penumbra.

The moon's shadow covers only a spot on the earth's surface about 180 English miles broad, when her diameter appears largest, and the sun's least; and the total darkness can extend no farther than the limits of the dark shadow. Yet the partial shadow or penumbra may then cover a circular space 4900 miles in diameter, within all which the sun is more or less eclipsed, as the places are less or more distant from the centre of the penumbra. When the moon changes exactly in the node, the penumbra is circular on the earth at the middle of the general eclipse, because at

Theoretical Astronomy.

that time it falls perpendicularly on the earth's surface; but at every other moment it falls obliquely, and will therefore be elliptical; and the more so as the time is longer before or after the middle of the general eclipse; and then much greater portions of the earth's surface are involved in the penumbra.

To make several of the above and other phenomena plainer, let S (fig. 52) be the sun, E the earth, M the moon, and AMP the moon's orbit. Draw the straight line W *e* from the western side of the sun at W, touching the western side of the moon at *c*, and the earth at *e*: draw also the straight line V *d* from the eastern side of the sun at V, touching the eastern side of the moon at *d*, and the earth at *e*: the dark space *c e d* included between these lines is the moon's shadow, ending in a point at *e*, on the surface of the earth, because in this figure the moon is supposed to be at her mean distance from the earth. Had the moon been in her perigee, the shadow would have covered a space on the surface of the earth of about 180 miles in diameter, to all places within which space the eclipse would have been total. Had she been in her apogee, the shadow would have terminated in a point above *e*, and to an observer at *e* the sun would have been eclipsed annularly. Draw the straight lines W X *dh* and V X *cg*, touching the contrary sides of the sun and moon, and ending on the earth at *a* and *b*; draw also the straight line SXM from the centre of the sun's disk, through the moon's centre to the earth, and suppose the two former lines W X *dh* and V X *cg* to revolve on the line SXM as an axis, and the points *a* and *b* will describe the limits of the penumbra TT on the earth's surface, including the large space *a b a*, within which the sun appears more or less eclipsed, according as the places are more or less distant from the verge of the penumbra *a b*.

Draw the right line *y* 12 across the sun's disk, perpendicular to SXM the axis of the penumbra; then divide the line *y* 12 into twelve equal parts, as in the figure, for the twelve digits or equal parts of the sun's diameter; and at equal distances from the centre of the penumbra at *e* (on the earth's surface YY) to its edge *a b*, draw twelve concentric circles.

To an observer on the earth at *b*, the eastern limb of the moon at *d* seems to touch the western limb of the sun at W when the moon is at M, and the sun's eclipse begins at *b*; but at the same moment of absolute time, to an observer at *a*, the western edge of the moon at *c* leaves the eastern edge of the sun at V, and the eclipse ends. At the very same instant, to all those who live on the circle next to *ab*, the moon cuts off or darkens a twelfth part of the sun, and eclipses him one digit; to those who live on the next interior circle, the moon cuts off two twelfth parts of the sun; to those on the following circle, three parts; and so on to the centre at *e*, where the sun is centrally eclipsed. The different appearances of the eclipse, as seen by spectators in these different situations, with regard to the centre of the shadow, are represented in fig. 54, under which figure there is a scale of hours and minutes, to show at a mean state how long it is from the beginning to the end of a central eclipse of the sun on the parallel of London, and how many digits are eclipsed at any particular time from the beginning at A to the middle at B or the end at C. Thus, in 16 minutes from the beginning, the sun is two digits eclipsed; in an hour and five minutes, eight digits; and in an hour and 37 minutes, 12 digits.

Having determined the diameter of the moon's shadow at the earth, and the limits within which eclipses of the sun can take place, the next object is to determine the time of their commencement and termination. If the position of the observer were on the moon instead of the surface of the earth, our solar eclipses would appear to him as eclipses of the earth, and they would commence at the instant when the earth's disk began to penetrate the lunar shadow. A spectator so situated might therefore compute all the circumstances of a terrestrial eclipse in exactly the same manner in which we compute those of the moon; the same formulæ would suffice, with the slight modifications which have already been made. But relatively to an observer placed on the earth the case is altogether different. To him the eclipse does not begin when the moon's shadow comes into contact with the earth's disk, but when it begins to obscure his station. This, therefore, is one circumstance which renders the computation of solar more complicated and difficult than that of lunar eclipses; for it is necessary not only to determine generally what portion of the terrestrial disk is covered by the shadow, but also its position relatively to the equator and to a given meridian, and likewise the path described by the centre and contour of the umbra and penumbra on the surface of the earth. There is another circumstance which still further augments the difficulty of the computation, namely, the position of the observer, on account of which it is necessary to introduce the particular conditions which depend on the parallax. In the case of a lunar eclipse, it is only necessary that the moon's disk enter the earth's shadow in order that the eclipse may be visible to any part of the terrestrial hemisphere opposite to the moon; but a solar eclipse may happen in some parts of the earth without being visible at others—a circumstance which is occasioned entirely by parallax.

Theoretical Astronomy.

When we abstract from the effects of parallax, or suppose the observer to be placed at the centre of the earth, the problem of determining the different circumstances of a solar eclipse is exactly the same as that relative to an eclipse of the moon. But when the spectator is supposed to be placed at the surface, the latitudes and longitudes corresponding to his situation are different from the geocentric latitudes and longitudes; and in order to adapt the formula from which the time is given to these new circumstances, it is necessary, as a preliminary step, to compute the corrections which must be applied in consequence of the effects of parallax in longitude and latitude. The chief circumstance, therefore, in which the calculation of solar eclipses differs from that of lunar, consists in its being necessary to compute the effect of parallax in the direction of the angular distances which form the data of the problem, in order to apply the requisite correction to the values of those distances furnished by the tables. The development of these computations belongs to Practical Astronomy.

The sun's ecliptic limits exceeding 17° 21′, while those of the moon are only 11° 26′, it follows that the eclipses of the sun must be much more frequent than those of the moon. Yet the lunar eclipses being visible to every part of the terrestrial hemisphere opposite to the sun, and those of the sun visible only to the small portion of the hemisphere on which the moon's shadow falls, it happens that for any particular place on the earth the lunar eclipses are much more frequently visible.

Number of eclipses in a year.

In any year the number of eclipses of both luminaries cannot be less than two, nor more than seven: the most usual number is four, and it is very rare to have more than six; for the sun passes through both the nodes but once a year, unless he passes through one of them in the beginning of the year; and if he does, he will pass through the same node again a little before the year is finished; because, as these points move 19½ degrees backwards every year, the sun will come to either of them 173 days after the other;

and when either node is within 17 degrees of the sun at the time of new moon, the sun will be eclipsed. At the subsequent opposition, the moon will be eclipsed in the other node, and come round to the next conjunction again ere the former node be 17 degrees past the sun, and will therefore eclipse him a second time. When three eclipses take place about either node, the like number generally happens about the opposite, as the sun comes to it in 173 days afterwards; and six lunations contain but four days more. Thus, there may be two eclipses of the sun and one of the moon about each of her nodes. But when the moon changes in one of the nodes, she cannot be near enough the other node at the next full to be eclipsed; and in six lunar months afterwards she will change nearer the other node: in these cases there can be but two eclipses in a year, and they are both of the sun.

The eclipses of the sun being of great importance for the determination of geographical longitudes, it is of consequence to be in possession of some easy method of assigning the time at which they may be expected to occur, in order to avoid the necessity of long and tedious calculations. This may be done in a very simple manner, by considering that if a time can be assigned after which the sun and moon occupy exactly or nearly the same positions with regard to the nodes of the lunar orbit, their motions after that interval will recommence under the same circumstances, and the eclipses be reproduced in the same order. Now, it has been shown (chap. iii. sect. 2) that the nodes of the lunar orbit retrograde at the rate of 19°·3286 in a year, consequently the time in which the sun returns to the moon's node is that which he requires to describe an arc of 360° — 19°·3286, or, as is found by a simple proportion, 346·619851 days. On comparing this with 29·5305887 days, the time of a lunation, it will be observed that these numbers are nearly in the ratio of 223 to 19, so that after 223 synodic revolutions the moon has returned 19 times to the same position relatively to the sun. But 223 synodic revolutions are completed in 18 mean solar years and 10 or 11 days, consequently after that interval all the eclipses, whether of the sun or the moon, return again in nearly the same order; which gives a very simple means of predicting them, since only 18 years of observation are required. This period was known to the astronomers of the remotest ages, and is generally supposed to be that which the Chaldeans distinguished by the name of *Saros*. (See PART I. of this article.)

But the ratio of 223 to 19 is not exact, and it is besides subject to variation from the secular inequalities of the sun and moon, by reason of which the rates of their mean motions are sensibly changed. Discordancies will hence arise; and in the course of time the order of eclipses observed in one of these periods will require correction. But the variations are slow and gradual; the lunisolar periods may, therefore, continue to be employed when approximative results only are required. When rigorous accuracy is wanted, recourse must be had to computation from the astronomical tables.

Occultations.

Occultations of planets and stars by the moon are phenomena of which the calculation depends on exactly the same principles, and is even made by the help of the same formulæ, as the eclipses of the sun. Let E (fig. 55) denote the centre of the earth, M that of the moon, and S a star or planet concealed by the moon; the straight line SM will represent the axis of the lunar shadow, that is to say, the portion of space which the rays proceeding from the star cannot reach in consequence of their being intercepted by the moon; and the angle EMO (EO being perpendicular to SM) will be the apparent distance of the centre of the shadow from the centre of the earth. The expression for this angle in a function of the time is obtained in exactly the same manner as in solar eclipses; and by equating it with the different values of the angle which correspond to the different phases of the occultation, and regarding the time as the unknown quantity, the epochs will be obtained at which the phases take place. There is only one circumstance which renders a slight modification of the formulæ necessary. In computing the angle SEM, or the apparent distance of the centres of the star and moon seen from the centre of the earth, that distance may be regarded in solar eclipses as the hypothenuse of a right-angled triangle, the sides of which are respectively the latitude of the moon, and the difference between the longitudes of the moon and sun. But in occultations of the planets or stars, the star may be out of the ecliptic, and consequently its latitude not zero; so that the sides of the right-angled triangle, of which the apparent distance of the centres is the hypothenuse, are the difference of latitude of the star and moon, and the difference of longitude reduced to the moon's place, that is to say, multiplied by the cosine of the moon's latitude. It is evident that any of the planets may suffer an occultation by the moon; but with regard to the fixed stars, it is only those which are situated at a distance from the ecliptic not greater than the moon's extreme latitude, that can ever be hid by the interposition of the lunar disk.

The following is a list of all the solar eclipses that will be visible in this country during the present century. The time of the commencement of the eclipse, and the number of digits eclipsed, are computed for the middle of England. (See Baily's *Tables*, &c. p. 52.)

Theoretical Astronomy

CHAP. IV.

OF THE PLANETS.

SECT. I.—*General Phenomena of the Planetary Motions.*

Having now described the motions and explained the phenomena of the sun and moon, our attention will be next occupied by the planets, those no less interesting bodies, whose remarkable peculiarities of apparent motion have attracted the curiosity, and formed a principal object of the labours, of astronomers in all ages. The sun and moon move among the stars always in the same direction, and with velocities nearly uniform; but the planets, though their apparent motions are most frequently from west to east, sometimes appear to have no proper motions, or to remain stationary among the fixed stars; at other times they appear to move in a contrary direction, or to retrograde; and hence the earth cannot be the centre of the planetary orbits. The determination of that centre, and the order of distance in which the orbits of the different planets are placed around it, is comparatively an easy task since the telescope and micrometer have made us acquainted with the phases and variations of the apparent diameters of the planets; but the ancients, who were guided by the apparent motions alone, found greater difficulty in extricating the elements of their theories from observations, and in framing hypotheses by which the phenomena could be represented with tolerable accuracy. The different hypotheses which have been proposed for this purpose are called, with sufficient impropriety, *Systems of the World.*

In order to obtain a general notion of the path traced by a planet in the heavens, it is necessary to attend closely to the various phenomena which it exhibits. As an example, we may take Venus, the most brilliant and remarkable of all the planets.

A slight attention to the position of Venus, continued a few days, suffices to show that she changes her place with considerable rapidity among the fixed stars. If we observe her in the evening, we shall soon find that her greatest distance from the sun never exceeds an arc of about 47°; that after attaining this distance she begins again to approach the sun, the time which she continues above the horizon after sunset gradually diminishing, till at last she sets simultaneously with the sun, and is lost in the effulgence of his rays. From the circumstance of her appearing in the evening, and not remaining visible more than about three hours after the sun has descended below the horizon, Venus has obtained the name of Ἑσπερος, Hesperus, or the evening star; sometimes also she is called the shepherd's star.

A few days after the evening star has disappeared, a brilliant star is observed in the morning preceding the sun in the east, which was not seen while Venus followed him in the west. At first it rises only a few minutes before the sun, but every succeeding morning somewhat earlier, till its distance from him is between 45 and 47 degrees. It then begins gradually to fall back; its elongation or distance from the sun becomes less and less, till it approaches so near to him as to be again lost in his rays. This has been called Φωσφορος, Lucifer, or the morning star.

Hesperus and Lucifer were long regarded as different stars. It could not fail, however, to be remarked, that during the time the first continues to shine in the evening, the other is invisible in the morning, and as soon as the bright harbinger of day makes its appearance, the evening star ceases to be visible. It was, besides, observed that the one star disappears within a very short distance from the sun, and that the other, when first seen after its periodical disappearance, is equally near to him on the opposite side. The distance which each recedes from the sun was likewise remarked to be the same; and the times during which they are alternately visible were found to be equal. These phenomena led some bolder genius to affirm that Hesperus and Lucifer are the same star, which is alternately visible in the morning and evening, according as it precedes or falls behind the sun. Obvious as this conclusion is, it was not arrived at till after many ages of reflection and experience.

Theoretical Astronomy.

Since Venus never appears at a greater distance from the sun than about 47°, it is evident that the earth is neither the centre of her orbit, nor included within it; for in either case she would sometimes, like the moon, be seen in opposition to the sun. From the appearances which have as yet been described, it can only be inferred that Venus is a satellite of the sun, and that her orbit is carried along with him in his annual revolution in the ecliptic; but the phenomena which she presents when seen through the telescope afford the means of deducing more definite conclusions.

When Venus, after having been for some time visible in the evening, begins to approach the sun, she appears through the telescope as a fine luminous crescent, the horns of which are turned towards the east, and which becomes narrower as her distance from the sun diminishes. After she has passed the sun, and begins to appear in the morning, the horns of the crescent are turned towards the west, and its breadth gradually enlarges in proportion as the planet recedes from the sun, till she has gained her greatest elongation, when her disk becomes a semicircle. After this she begins to approach the sun with an accelerated motion, and her disk becomes gibbous, the illuminated or visible part being greater than a semicircle; and when she overtakes the sun, her disk has attained the dimensions of a full orb. Having passed the sun, the orb begins again to contract, and passes through the same gradation of changes on the eastern side of the sun, till the planet comes again into conjunction, when it vanishes entirely. All these phases, which nearly resemble those of the moon, are illustrated by fig. 56. When Venus is in the superior conjunction at A, or in the same straight line with the sun, she presents the full orb, because the hemisphere enlightened by the sun is turned directly towards the earth at E. Arrived at B, the illuminated hemisphere is not turned exactly towards the earth, and consequently one side of her orb must appear elliptical, the major axis being to the minor as radius to the cosine of the inclination of the planes of illumination and vision, as was shown in explaining the phases of the moon. (Chap. iii. sect. 1.) At C, where the straight lines drawn from the planet to the earth and sun form a right angle, the minor axis of the ellipse vanishes, and we have the half-illuminated orb. At D only a small portion of the enlightened hemisphere is visible from E; and when the planet arrives at F, the inferior conjunction, her dark side is wholly turned towards the earth, and she is invisible.

Plate LXXXII. Fig. 56.

Mercury exhibits phenomena exactly analogous to those of Venus. Like Venus, he oscillates on opposite sides of the sun; but his oscillations are much quicker, and performed in a much smaller arc. His greatest elongation or distance from the sun does not exceed 28° 20′; so that he never appears above the horizon longer than an hour and 50 minutes after sunset or before sunrise. He emits a very vivid white light; but, by reason of his proximity to the sun, he is seldom visible to the naked eye. His phases resemble those of Venus, and he is frequently seen as a dark spot passing over the sun's disk.

Theoretical Astronomy.

From these phenomena several important conclusions may be drawn. In the first place, Mercury and Venus are opaque bodies, which are only visible in consequence of the sun's rays reflected from their surfaces. In the second place, their orbits are described about the sun, and do not embrace the earth, because both planets pass between the sun and the earth, and their digression from the sun never exceeds a certain limit. For this reason they are called *Inferior Planets*. In the third place, since the digressions of Venus are much more considerable than those of Mercury, it is obvious that her orbit includes that of Mercury. This last fact is established by other phenomena. Their angular velocities may be compared by means of the times which they respectively employ in returning to their conjunctions; and in this way it is found that the angular velocity of Mercury is nearly three times greater than that of Venus—a circumstance of itself sufficiently indicative of his greater proximity to the sun. But the occultation of one of these planets by the other furnishes a decisive evidence of the disposition of their orbits. On the 17th of May 1737 Mercury was observed to be occulted by Venus near their inferior conjunction; whence it follows that Venus is nearer the earth, and consequently at a greater distance from the sun. This fact was known to the Egyptians, and the name of the *Egyptian System* given to that theory according to which Mercury and Venus were regarded as satellites of the sun; but as the ancient astronomers were unacquainted with one of its strongest proofs, namely, the transits over the sun, and could only form inferences from the digressions, it was not generally adopted by them.

The revolution of Venus and Mercury about the sun may also be inferred from the variations of their apparent diameters, although, on account of the unequal distances of the sun from the earth, these variations are subject to considerable irregularities. When Venus approaches nearest to the earth, her apparent diameter subtends an angle of about 61″, while it does not amount to 10″ when she is at her greatest distance. The apparent diameter of Mercury varies from 12″ to 5″, indicating corresponding variations of distance. These variations of his apparent diameter are not sensible to the naked eye, on account of the irradiation which surrounds the disks of the planets, and which renders it impossible to form any correct judgment respecting the magnitudes of small luminous objects seen from so great a distance.

The phenomena of the other planets differ in some respects from those of Mercury and Venus. Instead of remaining constantly within a certain distance from the sun, their angles of elongation assume all possible values, and they are frequently seen in opposition, and consequently more distant from him than the earth is. Their orbits, therefore, embrace the earth; and as they are never observed in their conjunctions to pass, like the inferior planets, over the sun's disk, even when the direction of their motion traverses the sun, it follows that the sun is also included within their orbits. This fact is rendered certain by the appearance of their disks at the time when they are in conjunction. If they were then placed between the sun and the earth, their disks would appear cornicular, like those of Mercury and Venus; but they uniformly present a full orb at the time of their conjunction, and consequently the same hemisphere is presented to the earth and the sun, at least if, as is certain, they derive their light from him. They must therefore be situated beyond the sun. From the circumstance that their orbits include both the earth and the sun, they are called *Superior Planets*. In order to determine whether the sun or the earth is the centre of their motions, it will be convenient to have recourse to observations of their apparent diameters, which, if their orbits are circular, and have the earth in their centre, will always be of the same magnitude. But the apparent diameter of Mars gradually increases from his conjunction to his opposition; and therefore, since the distance of the planet is directly proportional to the magnitude of its apparent diameter, Mars is nearer to the earth at his opposition than at his conjunction. The variations of the apparent diameter of this planet are very considerable, the limits being 18″·28 and 3″·6; so that Mars is five times farther from the earth at his greatest distance than at his least. His orbit, therefore, cannot be a circle described about the earth. We might indeed suppose it to be an ellipse, or other elongated curve; but the enormous eccentricity which it would be necessary to assign to it renders this supposition extremely improbable. The analogy of Venus and Mercury will rather lead us to infer that the sun is the centre of his motion; and of this we have a geometrical proof in the circumstance that the difference of his greatest and least distances is equal to the diameter of the earth's orbit. Jupiter, Saturn, and Uranus, present exactly similar phenomena. We therefore conclude in the same manner that they are superior planets, circulating about the sun.

The order of distance in which the superior planets are disposed about the sun and the earth may be inferred either from the rate of their motion when they are in opposition with the sun (it being natural to suppose that their velocities will diminish in proportion to their distances or the magnitude of the orbit which they describe), or it may be determined from the variation of their apparent diameters. Now, the apparent diameters at the conjunctions and oppositions are nearly in the following ratio: those of Mars as 1 to 5, of Jupiter as 10 to 15, of Saturn as 1 to 1·23; hence the diameter of the terrestrial orbit is to the diameters of the orbits of Mars, Jupiter, and Saturn, as the difference of the preceding numbers is to their sum, or as unity to the numbers $1\frac{1}{2}$, 5, and $9\frac{1}{2}$. In this manner we find that Jupiter is at a much greater distance from the earth than Mars, and Saturn than Jupiter.

It has already been remarked that the apparent motions of the planets are not always in the same direction. Through the most considerable part of their orbits they move from west to east, according to the order of the signs; and their motion is most rapid when they are at the greatest distance from the earth. It gradually relaxes until the planet has reached its greatest eastern digression if it is an inferior planet, or its eastern quadrature if a superior one; after which its proper motion is slower than the sun's motion in the ecliptic. In the course of a short time the planet seems stationary among the stars for some days, its right ascension undergoing scarcely any variation. In the course of a few days more, however, it begins again sensibly to change its place, and now moves in an opposite direction, or retrogrades. This retrograde motion continues to be accelerated as the planet approaches its inferior conjunction, or its opposition, at which point it attains its maximum. After this it begins to be retarded; the planet becomes a second time stationary, and then assumes its direct motion, to pass through another series of similar changes. The arc and time of retrogradation are different for each of the planets, being greatest in the case of those which are nearest the earth, and least for those which are at the greatest distance.

These phenomena, which are called the *Stations* and *Retrogradations* of the planets, were observed with great attention by the ancients and the astronomers of the middle ages, to whom their explanation gave much embarrassment on account of their being incompatible with

the supposition that the earth is the centre of the celestial motions. In fact, if the earth is supposed immovable, the path described by the planets is a curve so extremely complicated and irregular, that Aristotle, and even Riccioli, who lived in an age when the celestial motions were much better known, were reduced to the necessity of supposing a genius or angel to reside in each of the planets, directing its motions as the mind of man directs the motions of his body. Suppose the earth to be at rest in E (fig. 57), the orbit of a superior planet will resemble the curve *abcdef*, &c. When the planet arrives at *b*, before it comes into opposition with the sun at A it becomes stationary. From *b* to *c* it retrogrades, and is again stationary at *c*. Its motion then becomes direct, and its distance from the earth continues to increase while it runs through the arc *defgh*, and till it arrives at *h*, and is in conjunction with the sun at B. It is then at its greatest distance, and in passing through the arc *klm* continues to approach the earth till it arrives at *m*, in opposition with the sun at C. Here it exhibits the same phenomena as at the former opposition, becoming stationary, retrograding, &c.; and at every succeeding opposition describes a sort of node or loop, similar to *lmn*. Its path is thus made up of an infinity of nodes, and presents a sufficiently striking resemblance to an epicycloid. Fig. 58, which has been copied from Cassini into most of the elementary treatises of astronomy, represents the apparent motions of Saturn, Jupiter, and Mars, in respect of the earth.

Plate LXXXI. Fig. 57.

Such are the general phenomena presented by the motions of the planets. We must next endeavour to determine the nature of the curve described by each of them, and the law according to which it is described, in order to arrive at the solution of the principal problem of astronomy, viz. to express the position of the heavenly bodies in terms of the time reckoned from a given instant.

System of epicycles.

The first successful attempt to frame a system by means of which the motions of the planets might be numerically calculated, was made by Apollonius of Perga. Apollonius supposed that a planet, instead of describing a circle about the earth, moves in the circumference of a second circle, the centre of which is carried round the circumference of the first. Let us suppose two unequal circles, situated in the same plane, the greater of which ACB (fig. 59), which is called the *deferent*, carries on its circumference the centre of the smaller PRP′S, which is called the epicycle; and let us also suppose that each of these circles turns uniformly about its centre, according to the order of the signs, that is, from west to east. The earth is situated at E the centre of the deferent, and the planet whose motions we consider is placed on the circumference of the epicycle. The phenomena resulting from this disposition will be different according to the ratio of the velocities of the two circles. In the first place, suppose the velocities to be equal, and that at the first instant the planet is placed at P, the extremity of the straight line which joins the centres of the deferent and epicycle: the planet is then at its apogee, and it is evident that its apparent velocity is the greatest possible, being the sum of the velocities in the two circles. It is evident also that the apparent velocity of the planet will diminish as it approaches the lower extremity P′ of its epicycle, or its perigee, and that in this point it will vanish altogether, because the perigee is carried backwards in the direction RP′S by the motion of the epicycle with a velocity equal to that by which it is carried forward by the motion of the deferent. From this point the apparent motion will receive a gradual augmentation of velocity, till the planet arrives again at its apogee, where it will recommence a course perfectly similar to the preceding. In this case, therefore, the apparent motion of the planet, though alternately accelerated and retarded, will always be direct.

Plate LXXXII. Fig. 59.

Let us next suppose that the velocity of the epicycle is greater than that of the deferent, which is the hypothesis adopted by Apollonius and Ptolemy. From P to R the motion of the planet is direct. At the point R its path coincides with the tangent RE, and it would be stationary if the epicycle were immovable; but as the epicycle advances according to the order of the signs, the planet will continue to move directly till it arrives at the point π, where its retrograde motion in the epicycle, in the direction π P′, is equal to the direct motion in the deferent. At the perigee P′ the planet will retrograde, because the directions of the two motions are diametrically opposite, and the retrograde motion in the epicycle is greater than the direct motion in the deferent. At π' it becomes a second time stationary, after which it resumes its direct motion, precisely according to the actual phenomena.

Ptolemaic system.

Lastly, if we suppose the velocity of the deferent to be greater than that of the epicycle, there will be neither station nor retrogradation, and the planet will always advance in the same direction, but contrary to that of the motion of the deferent. This, in the Copernican system, would be the motion of the moon with reference to a spectator placed on the sun, and regarding the orbit of the earth about the sun as the deferent, and that of the moon about the earth as the epicycle; for then the velocity of the earth about the sun would be about thirty times greater than that of the moon about the earth.

This method of representing the geocentric motions of the planets was adopted and fully developed by Ptolemy, who assigned the ratios of the radii of the epicycles and deferents of each of the planets, and disposed the orbits in the manner most conformable to the apparent motions. It may be remarked that the absolute lengths of the radii are immaterial; it is only their relative lengths to which it is necessary to have regard. As observations were multiplied, and new inequalities in the motions of the planets detected, the system of simple epicycles was in most instances found insufficient to explain the phenomena. Double and triple systems were therefore introduced, in which the first epicycle was regarded as a second deferent carrying its own epicycle, the second epicycle as a third deferent, and so on, till every irregularity of motion was explained. It is easy to conceive all this mechanism, and even to reduce it to general formulæ; but although it affords considerable facility for calculation, it is much too complicated to have place in nature. It is now well known that the orbits of the planets are not epicycloids, but ellipses: nevertheless, at a time when the circle and straight line alone were admitted in the solution of geometrical problems, it was extremely natural to inquire whether any construction could be found, without employing other curves, to represent the planetary motions; and the system of epicycles which resulted from this inquiry will remain a perpetual monument of the ingenuity of its authors, Apollonius and Ptolemy.

In arranging the planetary system, Ptolemy placed the earth at the centre of the universe, and nearest to it the moon, whose synodic revolution is the shortest of all, being performed in 29½ days. Next to the moon he placed Mercury, who returns to his conjunctions in 116 days. After Mercury followed Venus, whose periodic time is 584 days. Beyond Venus he placed the sun, then Mars, next Jupiter, and lastly Saturn, beyond which is the sphere of the fixed stars. (See fig. 60.) Plato and some other philosophers had placed the orbit of the sun immediately after that of the moon, and Mercury and Venus beyond the sun, on account that these planets

Theoretical Astronomy.

were never seen on the solar disk. Ptolemy, however, remarked that this reason was inconclusive, because the planets might easily be supposed to pass between the sun and the earth, without appearing exactly on the sun's disk, in the same manner as the new moons do not always cause a solar eclipse. In the system of Ptolemy, it is, however, a matter of absolute indifference whether the orbits of these planets are placed above or below that of the sun, inasmuch as the phenomena are exactly the same in both dispositions. This fact doubtless furnishes a strong objection to his system, and might have led him, we are apt to suppose, to adopt the system of the ancient Egyptians with regard to Mercury and Venus, and place the sun at the common centre of their orbits. But it must be recollected that Ptolemy had no means of measuring the diameters of the planets, or of forming any accurate notions of their distances; he was unacquainted with the phases of Venus, which demonstrate the revolution of that planet about the sun; and, in short, knew of no phenomenon which could not be reconciled with his system. His object was solely to represent the apparent motions by a geometrical construction, and by such means as geometry at that time could legitimately employ; and this object he fully accomplished. He never regarded his system in any other light than as a mere hypothesis, by means of which the celestial phenomena could be reduced to calculation.

But while thus much must be conceded in favour of the system of Ptolemy, it must be confessed that scarcely any thing could well be imagined more complicated and cumbersome; more at variance with the simplicity which pervades the economy of nature, or, in a physical point of view, more absurd. Yet so prone is the human mind to cling to the ideas which have been first presented to it, and with so much difficulty are errors which have once obtained a firm footing eradicated, that, till the beginning of the 16th century, it was implicitly followed by astronomers of all countries. The glory of bursting the fetters of prejudice and authority, and of building the true system of the world on the ruins of a fabric which had been erected with so much address and labour, was reserved for Copernicus. This great man was led, by a profound meditation on the different hypotheses which had been imagined to account for the apparent motions of the heavenly bodies, to adopt the ideas of some of the ancients, and remove the earth from the centre of the world, ascribing to it a double motion of rotation about its own axis and of revolution about the sun. From some scattered hints contained in the writings of the ancient philosophers, Copernicus composed the system which retains his name; a system of the truth of which the complete development of the planetary theory has furnished the most convincing and satisfactory proofs. According to this system the sun is the common centre of the orbits of all the planets, which revolve around him in the following order:—Mercury, Venus, the Earth, Mars, Jupiter, and Saturn. Far beyond the orbit of Saturn he supposed the fixed stars to be placed, which formed the boundaries of the visible creation.

System of Copernicus.

Although the great simplicity and beauty of the Copernican system soon recommended it to the adoption of the most philosophical of the astronomers of that period, yet for a long time it met with considerable opposition. The most eminent of its opponents was the celebrated Tycho Brahe, who could never bring himself to adopt the supposition of the motion of the earth. The principal objections which he urged against it were the immense distance at which it is necessary to suppose the fixed stars to be placed, in order to account for the smallness, or rather the entire absence, of the annual parallax; the improbability that a heavy mass like the earth should have so rapid a motion; and some passages of Scripture which seem to suppose the motion of the sun and the immobility of the earth. Tycho, therefore, proposed another system, in which he endeavoured to retain the most essential advantages of the Copernican theory, and at the same time preserve the earth's stability. In the system of Tycho the earth is supposed to be the centre of the solar and lunar orbits, and the sun to be the centre of all the planetary orbits, the orbits of the two inferior planets being smaller, and those of the superior larger, than the orbit of the sun; a distinction which is necessary for the explanation of the conjunctions and oppositions. This disposition of the orbits will be understood by referring to fig. 61. The system of Tycho is far less philosophical than that of Copernicus, and he has therefore exposed himself to the charge of having made a retrograde movement in science; but it must be confessed that it affords a satisfactory explanation of all the phenomena, and that the objections which can be urged against it are not of an astronomical, but of a physical or mechanical nature. In fact, if the planets are supposed to revolve about the sun, it is absolutely indifferent, so far as regards the phenomena, whether the annual motion is ascribed to the sun or the earth; but it is a physical absurdity to suppose that the sun, with its whole train of attendant planets, revolves about the earth, which, in comparison of them, is a mere atom.

Tychonic system.

Theoretical Astronomy.

Taking the truth of the Copernican theory for granted, let us consider what effect the motion of the earth has upon the apparent motions of the other planets. Were the earth to stand still in any part of its orbit, the places of conjunction both in the superior and inferior semicircle, as also of the greatest elongation, and consequently the places of direct and retrograde motion, and of the stations of an inferior planet, would always be in the same part of the heavens; whereas, on account of the earth's motion, the places where these appearances happen are continually advancing forward in the ecliptic, according to the order of the signs. In fig. 62 let ABCD be the orbit of the earth; *efgh* that of Mercury; ☉ the sun; GFKI an arc of the ecliptic extended to the fixed stars. When the earth is at A, the sun's geocentric place is at F; and Mercury, in order to be in conjunction, must be in the line AF; that is, in his orbit he must be at *f* or *h*. Suppose him to be at *f* in his inferior semicircle: if the earth stood still at A, his next conjunction would be when he is in his superior semicircle at *h*; the places of his greatest elongation also would be at *e* and *g*, and in the ecliptic at E and G. But supposing the earth to go on in its orbit from A to B; the sun's geocentric place is now at K; and Mercury, in order to be in conjunction, ought to be in the line BK at *m*. As by the motion of the earth the places of Mercury's conjunctions are thus continually carried round in the ecliptic according to the order of the signs, so the places of his greatest elongations must also be carried forward in the same direction. Thus, when the earth is at A, the places of his greatest elongation from the sun are in the ecliptic E and G; the motion of the earth from A to B advances them forward from G to L and from E to I. But the geocentric motion of Mercury will best be seen in fig. 63. Here we have part of the extended ecliptic marked ♈, ♉, ♊, &c., in the centre of which S represents the sun, and round him are the orbits of Mercury and the Earth. The orbit of Mercury is divided into 11 equal parts, such as he goes through once in eight days; and the divisions are marked by numeral figures, 1, 2, 3, &c. Part of the orbit of the earth is like-

Effects of the earth's motion on the appearances of the planets.

Plate VII. Fig. 63.

Theoretical Astronomy.

wise divided into 22 equal arcs, each arc being as much as the earth goes through in eight days. The points of division are marked with the letters *a, b, c, d, e, f,* &c. and show as many several stations from whence Mercury may be viewed from the earth. Suppose then the planet to be at 1 and the earth at *a*; draw a line from *a* to 1, and it shows Mercury's geocentric place at A. In eight days he will have advanced to 2, and the earth to *b*; draw a line from 2 to *b*, and it shows his geocentric place at B. In other eight days he will have proceeded to 3, and the earth to *c*; a line drawn from 3 to *c* will show his geocentric place at C. In this manner, going through the figure, and drawing lines from the earth at *d, e, f, g,* &c. through 4, 5, 6, 7, &c. we shall find his geocentric places successively at the points D, E, F, G, &c. where we may observe, that from A to B, and from B to C, the motion is direct; from C to D, and from D to E, retrograde. In this figure 22 stations are marked in the earth's orbit from whence the planet may be viewed, corresponding to which there ought to be as many in the orbit of Mercury; but as the periodic time of that planet does not include so many intervals of eight days, his place is marked at the end of every eight days for two of his periodical revolutions; and to denote this, two numeral figures are placed at each division.

The geocentric motion of Venus may be explained in a similar manner; only, as the motion of Venus is much slower than that of Mercury, her conjunctions, oppositions, elongations, and stations, all return much less frequently than those of Mercury.

To explain the stationary appearances of the planets, it must be remembered, that the diameter of the earth's orbit, and even that of Saturn, are but mere points in comparison of the distance of the fixed stars; and therefore any two lines, though absolutely parallel, drawn at the distance of the diameter of Saturn's orbit from each other, would, if continued to the fixed stars, appear to us to terminate in the same point. Let, then, the two circles

Plate LXXXII

fig. 64 represent the orbits of Venus and of the Earth; let the lines AE, BF, CG, DH, be parallel to SP, we may nevertheless affirm, that if continued to the distance of the fixed stars, they would all terminate in the same point with the line SP. Suppose, then, Venus at E while the earth is at A, the visual ray by which she is seen is the line AE. Suppose again, that while Venus goes from E to F, the earth goes from A to B, the visual ray by which Venus is now seen is BF parallel to AE; and therefore Venus will be all that time stationary, appearing in that point of the heaven where SP, if extended, would terminate: this station is at her changing from direct to retrograde. Again, suppose, when the earth is at C, Venus is at G, and the visual line CG; if, while the earth goes from C to D, Venus goes from G to H, so that she is seen in the line DH parallel to CG, she will be all that time stationary, appearing in the point of the celestial sphere determined by the prolongation of SP. This station is at her changing from retrograde to direct; and both are in her inferior semicircle.

As the superior planets move in larger orbits than the earth, they can only be in conjunction with the sun when they are on the side opposite to the earth; as, on the other hand, they are in opposition to him when the earth is between the sun and them. They are in quadrature when their geocentric places are 90° distant from that of the sun. In order to understand their apparent motions, we shall suppose them to stand still in some part of their orbit while the earth makes a complete revolution; in which case any superior planet would have the following appearances:—1 While the earth is in its most distant semicircle, the motion of the planet will be direct. 2. While the earth is in its nearest semicircle, the planet will be retrograde. 3. While the earth is near those places of its orbit where a line drawn from the planet would be a tangent, it would appear to be stationary. Thus, in fig. 65, let *abcd* represent the orbit of the earth, S the Sun, EFG an arc of the orbit of Jupiter, ABC an arc of the ecliptic projected on the sphere of the fixed stars. Suppose Jupiter to continue at F, while the earth goes round in its orbit according to the order of the letters *abcd*. While the earth is in the semicircle most distant from Jupiter, going from *a* to *b* and from *b* to *c*, his motion in the heavens would appear direct, or from A to B and from B to C; but while the earth is in its nearest semicircle *cde*, the motion of Jupiter would appear retrograde from C to B and from B to A; for *a, b, c, d,* may be considered as so many different stations from whence an inhabitant of the earth would view Jupiter at different seasons of the year; and a straight line drawn from each of these stations through F, the place of Jupiter, and continued to the ecliptic, would show his apparent place there to be successively at A, B, C, B, A. While the earth is near the points of contact *a* and *c*, Jupiter would appear stationary, because the visual ray drawn through both planets does not sensibly differ from the tangent F*a* or F*c*. When the earth is at *b*, a line drawn from *b* through S and F to the ecliptic shows Jupiter to be in conjunction with the sun at B. When the earth is at *d*, a line drawn from *d* through S, continued to the ecliptic, would terminate in a point opposite to B; which shows Jupiter then to be in opposition to the sun; and thus it appears that his motion is direct when he is in conjunction, but retrograde when he is in opposition with the sun.

Theoretical Astronomy.

Plate LXXXIII.

The direct motion of a superior planet is more rapid the nearer it is to a conjunction, and slower as it approaches to a quadrature with the sun. Thus, in fig. 66, let ⊙ be the sun, the little circle round it the orbit of the earth, of which *abcdefg* is the most distant semicircle, OPQ an arc of the orbit of Jupiter, and ABCDEFG an arc of the ecliptic in the sphere of the fixed stars. If we suppose Jupiter to stand still at P, by the earth's motion from *a* to *g* he would appear to move directly from A to G, describing the unequal arcs AB, BC, CD, DE, EF, FG, in equal times. When the earth is at *d*, Jupiter is in conjunction with the sun at D, and there his direct motion is swiftest. When the earth is in that part of its orbit where a line drawn from Jupiter would touch it, as in the points *e* or *g*, Jupiter is nearly in quadrature with the sun; and the nearer the earth is to any of these points, the slower is the geocentric motion of Jupiter; for the arcs CD and DE are greater than BC or EF, and the arcs BC and EF are greater than AB or FG.

Plate LXXXII.

The retrograde motion of a superior planet is more rapid the nearer it is to an opposition, and slower as it approaches to a quadrature with the sun. Thus, let ⊙, fig. 67, be the sun, the little circle round it the orbit of the earth, whereof *ghiklmn* is the nearest semicircle, OPQ an arc of the orbit of Jupiter, NKG an arc of the ecliptic. If we suppose Jupiter to stand still at P, by the earth's motion from *g* to *n* he would appear to move from G to N, describing the unequal arcs GH, HI, IK, KL, LM, MN, in equal times. When the earth is at *k*, Jupiter appears at K in opposition with the sun, and there his retrograde motion is swiftest. When the earth is either at *g* or *n* (the points of contact of the tangents P*g* and P*n*), Jupiter is nearly in quadrature with the sun: and the nearer he is to either of these points the slower is his retrogradation; for the arcs IK and KL are greater than HI or LM, and the arcs HI and LM are greater than GH

Plate LXXXIII.

or MN. Since the direct motion is swiftest when the earth is at *d* (fig. 66), and continues diminishing till it changes to retrograde, it must be insensible near the time of change; and, in like manner, the retrograde motion being swiftest when the earth is in *k* (fig. 67), and diminishing gradually till it changes to direct, must also at the time of that change be insensible; for any motion gradually decreasing till it changes into a contrary one gradually increasing, must at the time of the change be altogether insensible.

Plate LXXXII. Plate LXXXIII.

The same changes in the apparent motions of this planet will also take place if we suppose him to advance slowly in his orbit; only they will happen successively when the earth is in different parts of its orbit, and consequently at different times of the year. Thus (fig. 65), let us suppose that while the earth goes round its orbit, Jupiter goes from F to G; the points of the earth's orbit from which Jupiter will now appear to be stationary will be *x* and *y*; and consequently his stations must be at a time of the year different from the former. Moreover, the conjunction of Jupiter with the sun will now be when the earth is at *f*, and his opposition when it is at *e*; for which reason these also will happen at times of the year different from those of the preceding opposition and conjunction. The motion of Saturn is so slow, that it occasions but little alteration either in the times or places of his conjunction or opposition; and the same will take place in a more eminent degree in Uranus; but the motion of Mars is so much swifter even than that of Jupiter, that both the times and places of his conjunctions and oppositions are thereby very much altered.

Fig. 68 exemplifies the geocentric motion of Jupiter in a very intelligible manner. In this figure ⊙ represents the sun; the circle 1, 2, 3, 4, the orbit of the earth, divided into twelve equal arcs for the twelve months of the year; PQ an arc of the orbit of Jupiter, equal to that which he describes in a year, and divided in like manner into twelve equal parts, each representing the arc he describes in a month. Now suppose the earth to be at 1 when Jupiter is at *a*, a line drawn through 1 and *a* shows Jupiter's place in the celestial ecliptic to be at A. In a month's time the earth will have moved from 1 to 2, Jupiter from *a* to *b*; and a line drawn from 2 to *b* will show his geocentric place to be in B. In another month the earth will be in 3, and Jupiter at *c*, and consequently his geocentric place will be at C; and in like manner his place may be found for the other months at D, E, F, &c. It is likewise easy to observe that his geocentric motion is direct in the arcs AB, BC, CD, DE; retrograde in EF, FG, GH, HI; and direct again in IK, KL, LM, MN. The inequality of his geocentric motion is likewise apparent from the figure.

Supposing the orbits of the planets to be circular, the points of station, and the extent and duration of the retrogradations, may be geometrically determined with great facility; but if we attempt to take into consideration all the inequalities of the orbits, the problem becomes one of extreme complication and difficulty. This, however, is the less to be regretted, on account that it is more a problem of curiosity than of any real importance, and the mean values which result from the supposition of circular orbits are more than sufficiently accurate for all the uses which are now made of these phenomena.

Let S, fig. 69, be the sun, E and V two planets (which we may suppose to be the Earth and Venus) revolving in their respective orbits in the times T and *t*: the problem is, to determine those points at which one of them, as seen from the other, will become stationary, and the extent of the arc through which it will appear to retrograde. Suppose the spectator to be placed at E, and V to be the point at which Venus is stationary. Also let the semidiameters of their orbits SE and SV be R and *r* respectively, the angle of digression SEV = φ, and the angle SVE = ψ. During a short time, at the station, the lines EV and *ev* (Ee and *Vv* being very small arcs) may be considered as parallel; therefore $\varphi = Suv = Sev + ESe = \varphi + \delta\varphi + ESe$, whence $\delta\varphi = -ESe$. In like manner $\psi = Sxe = Sve - VSv = \psi + \delta\psi - VSv$; whence $\delta\psi = VSv$. But as the orbits are described uniformly, $T : t :: VSv : ESe$, and consequently $T : t :: \delta\psi : \delta\varphi$. Now, the triangle SEV gives the equation $\sin.\psi = \frac{R}{r}\sin.\varphi$, from which, by differentiating, we get $\delta\psi \cos.\psi = \frac{R}{r}\delta\varphi \cos.\varphi$, and consequently $\delta\psi : \delta\varphi :: R\cos.\varphi : r\cos.\psi$. Comparing this with the above proportion, we have $T : t :: R\cos.\varphi : r\cos.\psi$, whence $r\cos.\psi = \frac{t}{T}R\cos.\varphi$. Taking the squares, and adding $r^2\sin.^2\psi = R^2\sin.^2\varphi$, there results

$$r^2T^2 = R^2(t^2\cos.^2\varphi + T^2\sin.^2\varphi),$$

whence we derive

$$\sin.\varphi = \frac{1}{R}\left(\frac{r^2T^2 - R^2t^2}{T^2 - t^2}\right)^{\frac{1}{2}};$$

or, if we suppose $\frac{r}{R} = r'$, and $\frac{t}{T} = t'$,

$$\sin.\varphi = \left\{\frac{(r'+t')(r'-t')}{(1+t')(1-t')}\right\}^{\frac{1}{2}}.$$

From this formula, all the circumstances connected with the stations and retrogradations are easily computed, when the diameter of the orbit and the periodic time of the planet are known. Thus, relatively to Venus, the quantity *r'*, that is, the ratio of the diameter of her orbit to that of the earth, is, as will be shown in next section, equal to 0·723, and $t' = \frac{224\cdot7}{365\cdot25} = 0\cdot6152$, whence $\sin.\varphi = \sqrt{\frac{1\cdot338\times\cdot108}{1\cdot615\times\cdot385}} = 0\cdot48208$; and $\varphi = 28°\ 49'$. The angle ψ is obtained from the equation $\sin.\psi = \frac{\sin.\varphi}{r'}$, which gives $\psi = 138°\ 11'$. The angle VSE at the sun, or the heliocentric distance of Venus and the Earth, which we shall designate by χ, is $180° - (\varphi + \psi) = 13°$. From this angle we likewise obtain the time from the station to the conjunction; for since the mean daily motion of Venus is 1° 36′ 7″·8, and that of the earth 59′ 8″·3, the relative daily motion is 36′ 59″·5, therefore the time from conjunction will be $\frac{13°}{36'\ 59''\cdot5}$, or about 21 days, and consequently the retrograde motion of Venus will continue about 42 days.

If in the equation $\sin.\varphi = \frac{1}{R}\left(\frac{r^2T^2 - R^2t^2}{T^2 - t^2}\right)$ we suppose $rT = Rt$, the angle φ vanishes; consequently there will be no regression, and the station will only be momentary at the inferior conjunction. In this case $r : R :: t : T$, or the distances of the planets are proportional to their periodic times. If Rt were greater than rT, φ would become imaginary, and the motion of the planet would always be direct. The stations and retrogradations are therefore consequences of that law of the system according to which the distances are to one another in a greater ratio than the periodic times.

The following table, given by Delambre (*Astronomie*, tome iii. p. 9), exhibits the elements of the stations and retrogradations of the planets, calculated from formulæ equivalent to the above.

	Mercury.	Venus.	Mars.	Ceres.	Jupiter.	Saturn.	Uranus.
φ	18° 12′	28° 51′	136° 12′	126° 7′	115° 35′	108° 47′	103° 15′

SECT. II.—*Of the Orbits of the Planets.*

In determining the elements of the orbits of the sun and moon, the labour of the astronomer is facilitated by the circumstance that the earth, at which his observations are made, either is, or may be regarded as, the centre of motion. But in the case of the planets, the sun, and not the earth, is situated in the centre of their orbits, and consequently the elements of those orbits must be determined from the measurement of certain linear and angular distances from the sun: it is therefore necessary, as a preliminary step, to convert the geocentric into heliocentric observations, that is, to deduce the true place of a planet as seen from the sun, from its apparent place as seen from the earth. On this account the determination of the planetary orbits is attended with somewhat greater difficulties than those which present themselves in the cases of the sun and moon.

1. *Nodes and Inclinations of the Planetary Orbits.*— Conformably with the plan which has been followed in the two preceding chapters, we will first consider those elements which determine the position of the plane of the orbit of a planet; and then those which regard the orbit itself, that is to say, the elements and position of the ellipse which the planet describes. When these are known, and the astronomer is also acquainted with the mean motion, or the time of the periodic revolution of the planet, and the instant at which it occupied any given point of its orbit, he is in a condition to assign the epoch at which it will again occupy the same or any other given point; and this comprehends the complete solution of the problem which he proposes to himself. It is proper, however, to remark here, that although this method of considering the elements separately is extremely convenient, perhaps indispensable, for the purpose of illustration, it is neither that which the practical astronomer follows, nor that by which the various truths which compose the actual system of theoretical astronomy were discovered. No discovery in astronomy has perhaps ever been made by a direct process. The elements first obtained from the observations are imperfect and inexact, and it is only by successive and frequently laborious approximations that they are advanced to accuracy. Hypotheses are first framed to account for or classify the phenomena; the results of these arbitrary suppositions are computed and compared with new observations; and the differences which are found to exist between the computed and observed quantities serve to verify or correct the assumption, or suggest other approximations still nearer the truth. In astronomy, as Woodhouse remarks, scarcely one element is presented simple and unmixed with others. Its value, when first disengaged, must partake of the uncertainty to which the other elements are subject, and can be supposed to be settled to a tolerable degree of exactness only after multiplied observations and many revisions. There are no simple theorems for determining at once the parallax of the sun, or the heliocentric latitude of a planet.

To give a general idea of the method of reducing geocentric to heliocentric longitudes and latitudes, let S (fig. 70) be the sun, E the earth, P the place of a planet in its orbit NP, NA the ecliptic, and N the ascending node, or that point of the ecliptic through which the planet passes when it comes to the north of that plane. Let S♈, E♈, be drawn from S and E to the first point of Aries; these lines being parallel, and representing the direction of one of the axes of co-ordinates to which the places of the planet are referred. Let also PL be drawn perpendicular to the ecliptic, and the other lines as in the figure. It is easy to see that as NPC, NLA are regarded as the intersections of the planes of the orbits of the earth and the planet with the celestial sphere, the centre of which is occupied by the sun, they are portions of great circles; and consequently every question relative to the position of the planet may be resolved by the formulæ of spherical trigonometry. In fact, PL being a circle of latitude, the arc ♈NL is the *Heliocentric Longitude* of the planet, ♈N the longitude of the ascending node, and the spherical angle PNL the inclination of the orbit. In order that the longitude of the planet in its orbit may not differ greatly from its longitude referred to the ecliptic, the former is not reckoned from the node N, but from another point equally distant from the node with the vernal point ♈; so that the longitude of the planet is obtained by adding NP to the longitude of the node. The magnitude of the planet thus reckoned is usually called the longitude in the orbit. The latitude also depends immediately on the distance NP of the planet from the ascending node; hence NP is called the *Argument of the Latitude;* and the difference between the longitudes in the orbit and ecliptic, that is, NP—NL, is called the *Reduction to the Ecliptic.* The angle PEL, or the planet's apparent distance from the ecliptic to an observer at E, is the *Geocentric Latitude;* PSL, its distance from the ecliptic when viewed from the sun, is its *Heliocentric Latitude.* It is evident from the mere inspection of the diagram, that ♈EL and ♈SL are the geocentric and heliocentric longitudes respectively. The angles of the triangle ESL, from which the reductions are computed, being of very frequent use in practical astronomy, have received certain technical denominations with which it is convenient to be acquainted. The angle LES, which is the difference between ♈EL and ♈ES, the geocentric longitudes of the planet and the sun, is called the angle of *Elongation;* ESL, the angle at the sun, is called the angle of *Commutation;* and SLE, which is the difference between the heliocentric and geocentric longitudes, is called the *Annual Parallax,* or the *Prosthaphæresis of the Orbit.* In the case of an inferior planet, the annual parallax SLE may have any value between zero and 360°; but if the planet be a superior one, the greatest value of the annual parallax has place when the straight line drawn from the planet to the

earth is a tangent to the earth's orbit. In any other situation of the planet the sine of the annual parallax will be to the sine of the elongation as SE to SL.

In order to determine the position of the orbit of a planet relatively to the ecliptic, it is necessary to discover in the first place the position of the nodes. The longitude of the node is the heliocentric longitude of the planet at the instant when it is in the ecliptic, and its geocentric and heliocentric latitudes are consequently both equal to zero. If then, at the same instant, the planet should happen to be in opposition with the sun, or (if an inferior one) in its inferior conjunction, its geocentric longitude, which is equal to the longitude of the sun + 180°, would be the heliocentric longitude of the node. But it can happen very rarely that the latitude of a planet is zero at the time of its opposition or conjunction, especially with regard to those of which the periodic times are considerable. Mercury and Venus, indeed, by passing oftener through their nodes within a given time, afford more chances of the occurrence of the phenomenon; and it does occur occasionally under very favourable circumstances when those planets pass over the disk of the sun, for at such times the latitude must be very small, that is, the planet must be very near its node. But this simple method of determining the heliocentric longitude of the node, although it may frequently be had recourse to in the case of Mercury, can seldom be practised with regard to Venus, and is of no use whatever in the cases of the other planets, because, on account of the greater length of their times of revolution, the oppositions and passages through the node take place simultaneously only after very long intervals.

Leaving, therefore, out of consideration the circumstance of opposition, let us inquire what other means are in our possession for determining the longitude of the node. It would be by an extraordinary chance that a planet should happen to be observed at the precise instant of its passage through its node; but if observed when very near it, the diurnal variations of latitude afford data for determining that instant by interpolation. Suppose, then, the planet to be in its node at N: the angle ΥEN is obtained from observation, being the geocentric longitude of the node; and ΥES, the longitude of the sun, is known from the solar tables. Hence, in the triangle ENS the angle SEN = ΥEN − ΥES is known, as is also the side SE, which is the sun's distance from the earth. If, therefore, the angle at the planet, that is ENS, can be found, every part of the triangle will be determined, and we shall then have the heliocentric longitude ΥSN (equal to 180° − ESN + ΥES), and also the radius vector SN, or the distance of the planet from the sun. Now, the sides of a triangle being proportional to the sines of their opposite angles, $\frac{SN}{SE} = \frac{\text{sin. SEN}}{\text{sin. ENS}} = \frac{\text{sin.}(\Upsilon EN - \Upsilon ES)}{\text{sin.}(\Upsilon SN - \Upsilon EN)}$; but from this equation nothing can be deduced, inasmuch as it contains two unknown quantities, SN and ΥSN. Suppose, however, that the planet is observed a second time in its passage through the same node, and that the earth is then in another part of its orbit at *e*: this second observation will furnish another equation, viz. $\frac{SN}{Se} = \frac{\text{sin. } SeN}{\text{sin. } eNS} = \frac{\text{sin.}(\Upsilon eN - \Upsilon eS)}{\text{sin.}(\Upsilon SN - \Upsilon eN)}$, exactly similar to the former, and in which *Se* is equal to SE. If, then, we suppose the place of the node has not sensibly changed in the interval between the two observations, this last equation will furnish a second relation between the two unknown quantities SN and ΥSN, by combining which with the former, the values of both those quantities may be determined. By repeating the same observation, it will be seen whether the place of the node is fixed, or is subject to any other variation than that which arises from the precession of the equinoxes. Its variation, if it does vary, can only be determined by observations made at distant epochs.

When the longitude of the node has been determined in this manner, it will be easy to deduce the inclination of the orbit. For this purpose the planet may be observed at the time when the sun's longitude is equal to that of the node, and the earth is consequently situated in the line of the nodes. By this observation the elongation of the planet, which is then PEN (fig. 71), is given, as also its geocentric latitude PEL. Now, by reason of the right-angled triangles PEL and PSL, we have PL = EL tan. PEL = SL tan. PSL, consequently tan. PSL $= \frac{EL}{SL}$ tan. PEL; but EL : SL : : sin. LSN : sin. LES, therefore tan. PSL $= \frac{\text{sin. LSN}}{\text{sin. LES}}$ tan. PEL. Now, by Napier's rules for circular parts, the right-angled spherical triangle PNL gives also sin. NL = cot. PNL tan. PL; whence tan. PL = sin. NL tan. PNL; or, since tan. PL = tan. PSL, and sin. NL = sin. LSN, therefore tan. PSL = sin. LSN tan. PNL. By equating these two values of tan. PSL, we have

Plate LXXXIII.

$$\text{sin. LSN tan. PNL} = \frac{\text{sin. LSN}}{\text{sin. LES}} \text{ tan. PEL};$$

therefore, ultimately,

$$\text{tan. PNL} = \frac{\text{tan. PEL}}{\text{sin. LES}};$$

that is, the inclination of the orbit is given in terms of the geocentric latitude and the longitude of the node.

The instant at which the sun is in the node of a planet's orbit cannot be easily seized; but the sun's mean motion being known, if his longitude is observed when it is nearly equal to that of the node, the time at which he passes through it may be determined with all the necessary accuracy by a simple proportion. It requires also to be remarked that the above method of determining the inclination takes it for granted that the position of the node is exactly known; but even should some uncertainty remain regarding this element, the resulting inclination would scarcely be affected in any sensible degree by a slight error, especially if at the time of the observation the planet is not very distant from its quadratures. In fact, if we make PNL = I, PEL = λ, and LES = φ, the above equation becomes $\text{tan. I} = \frac{\text{tan. } \lambda}{\text{sin. } \varphi}$, which being differentiated with respect to I and φ, gives d tan. I $= -\frac{d\varphi \cos.\varphi \text{ tan.}\lambda}{\text{sin.}^2\varphi}$. But d tan. I $= \frac{dI}{\text{cos.}^2 I}$, and from the equation itself we derive $\text{cos.}^2 I = \frac{\text{sin.}^2\varphi}{\text{sin.}^2\varphi + \text{tan.}^2\lambda}$; therefore, by substituting

$$dI = -\frac{d\varphi \cos.\varphi \text{ tan.}\lambda}{\text{sin.}^2\varphi + \text{tan.}^2\lambda}$$

From this it is evident that the error of inclination resulting from an erroneous position of the node will be smaller in proportion as φ is greater, and will disappear altogether when φ (that is, LES or the geocentric distance of the planet from its node) is 90°, that is to say, at the quadratures.

The process now explained for determining the position of the nodes gives at the same time the length of

the radius vector SN; and, in consequence of certain relations which will be pointed out in the present section, all the other elements of the orbit may be deduced from simple observations of the passages of a planet through its nodes. But when approximate values of these elements are known, the heliocentric longitudes and latitudes may be found from geocentric observations of various kinds. If, therefore, the planet is observed several times before and after its passage through the node, the diurnal variations of longitude and latitude (which we at present suppose to be known very nearly) will give by interpolation the instant at which the latitude was nothing, and the heliocentric longitude, computed for that instant, will give the place of the node. By means of this more accurate determination the other elements may be corrected; and on repeating the same process with the corrected values, the longitude of the node will be obtained with still greater precision. These indirect methods of correcting the elements by one another were first employed by Kepler, and are of extensive application in every department of astronomy. They lead to more exact values of the elements of the planetary orbits than could be obtained from any direct method whatever.

As the passage of a planet through either of its nodes takes place only once during each periodic revolution, a remote planet, like Uranus, which moves very slowly, can very seldom be observed in those positions. Astronomers have therefore sedulously employed themselves in devising other methods by which all the elements of a planet's orbit may be discovered when a very small portion of it has been made known by observation. But these methods are the results of profound mathematical theory, based on the principle of Universal Gravitation, and could not therefore be properly explained in this place. Their application belongs to Practical Astronomy.

When the longitudes of the nodes of the planetary orbits are deduced by the methods explained above from ancient and modern observations, it is found that the nodes are not altogether fixed, but that, in respect of the fixed stars, they retrograde, or move from east to west; but their motion is so slow, that, although it is in reality, like every motion of the system, alternately accelerated and retarded, it may be regarded as uniform during a very long period of time. The inclinations of the orbits also undergo small variations, scarcely sensible to observation. The retrograde motion of the nodes of the planets, exactly analogous to that of the nodes of the moon, is a necessary consequence of the mutual gravitation of all the planetary bodies. The same is the case with the variations of inclination, of which the period and limits can only be calculated from the same theory to which we owe the knowledge of their existence. It is only indeed by the aid of the theories of Physical Astronomy that the greater part of these small secular variations can be disengaged from the periodic inequalities.

The following table exhibits the inclinations of the orbits of the planets, the positions of their nodes, and the variations of those elements. For the old planets the epoch is the commencement of the present century, that is to say, midnight preceding the 1st of January 1801. For Vesta, Juno, Ceres, and Pallas, the epoch is 1820. The annual increment of the longitude of the node is referred of course to the equinoctial point of Aries: to find its motion in respect of the fixed stars, it is only necessary to subtract the precession of the equinoxes, or 50″·1, from the numbers given in the table.

Names.	Inclination.	Secular Variation of Inclination.	Longitude of Ascending Node.	Annual Variation of Longitude of Node.
Mercury.....	7° 0′ 9″·1	+ 18″·1828	45° 57′ 30″·9	+ 42″·3

2. *Of the Figures of the Orbits.*—After the position of the plane of a planet's orbit in space has been determined, it remains to trace its path on that plane, or to determine the figure and elements of the orbit itself. This, it is evident, may be accomplished, if we are in possession of the means of assigning, at any instant, the planet's distance from a fixed point in the plane of its orbit, and likewise the angle formed by the radius vector with a straight line given by position on the same plane. With these data a series of points may be laid down, representing the positions successively occupied by the planet; and the curve formed by joining them together will represent the orbit. Now, when the place of the nodes and the inclination are known, the radius vector and elongation may be computed by the rules of spherical trigonometry from a single observation of the planet's geocentric latitude and longitude at any epoch whatever; but by making the observations when the planet occupies certain situations of its orbit with respect to the earth, the difficulties attending the computation may be in a great measure eluded. If a planet, for example, is observed at the time of its opposition or conjunction, there will be no occasion for a previous deduction of the heliocentric from the geocentric longitude; because, in either of those cases, the radius vector of the planet, and the straight line EP (fig. 72) drawn from it to the observer, are projected on the plane of the ecliptic in the same straight line ESL; and consequently the planet, whether seen from the earth or the sun, is referred to the same point of the ecliptic, excepting indeed the inferior planets, which in their inferior conjunctions are referred to points diametrically opposite. Let P, therefore, be the place of a planet in opposition; then, in the spherical triangle PNL, right-angled at L, the side NL, being the longitude of the planet minus that of the node, is given by observation (the longitude of the node being supposed to be previously determined); the inclination PNL is also known; therefore, by Napier's rules,

Plate LXXXIV.

$$\text{tan. PN} = \frac{\text{tan. NL}}{\text{cos. PNL}};$$

that is, the elongation of the planet is given in terms of its longitude and the inclination of its orbit. The same

Theoretical Astronomy.

triangle PNL also affords data for determining the radius vector: for tan. PL = tan PNL sin. NL; but PL is the measure of the angle PSL, and consequently PSL, the heliocentric latitude, also becomes known. Now, in the triangle PES the angle PES is given by observation, therefore EPS (= PSL — PES) is also given; but PS : SE :: sin. PES : sin. EPS, whence $PS = SE \frac{\text{sin. PES}}{\text{sin. EPS}}$, or the radius vector is found in terms of the sun's distance from the earth and given angles.

In consequence of the incommensurable relation subsisting between the times of the periodic revolutions of the planets and that of the earth, the successive oppositions and conjunctions never take place at the same points of the orbits; therefore, by making a number of similar observations, as many different angles of elongation and radii vectores will be found, which, unless the orbits are circular, will all have different values. By computing, therefore, the values of these radii vectores in terms of the greater axis of the earth's orbit, and laying them down in their true positions round the sun, we shall obtain an approximation to the curve described by the planet on the plane of its orbit. A few observations of this sort will suffice to show that the orbit is eccentric; and as we have already seen that the solar orbit is an ellipse, analogy will immediately suggest the probability that that of the planet is also an ellipse, having the sun in one of its foci. It is easy to determine whether this be the case or otherwise. Three points given by position on a plane completely determine an ellipse of which a focus is known: having therefore computed an ellipse which satisfies three observations of a planet, its periphery, if the hypothesis of elliptic motion is correct, will comprehend all the places of the same planet computed from any other observations. Now, it is found that this is what takes place with regard to every one of the planets; hence results the first of the three laws discovered by Kepler which form the basis of the whole system of modern astronomy, namely, that the *orbits of the planets are ellipses, of which the sun occupies one of the foci.*

First law of Kepler.

By a comparison of the sectors formed by two contiguous radii vectores and the arcs included between them, with the time consumed by the planet in describing those arcs, Kepler was led to the discovery of the second great law of the planetary motions, namely, that *the areas described by the radius vector of a planet are proportional to the times employed in describing them.* The data from which this important conclusion was deduced were not rigorously exact; but the fact itself has been confirmed by an infinity of observations since the time of Kepler; and Newton, by the application of geometry to dynamics, demonstrated that it is *necessarily* true of all motions regulated by a central force, whatever the nature of that force may be.

Second law of Kepler.

Kepler having, by means of the most laborious computations, established the existence of these two laws with regard to each of the planets separately, next undertook to discover whether any analogy could be found regulating their mean distances from the sun. As there were only six planets known in his time, he commenced his investigation by comparing the intervals between their respective orbits with the five regular geometrical solids. Having failed in this speculation, and in various others suggested by a mind equally fertile and persevering, he at length, by a happy inspiration of genius, thought of comparing the mean distances of the planets with their respective periods of revolution, and soon perceived that the numbers which represent the periodic times of the planets, beginning with Mercury and ending with Saturn, increase in a much greater ratio than those representing their mean distances from the sun. Jupiter, for example, is *five* times more distant from the sun than the earth is; but his period is *twelve* times greater than that of the earth. Kepler then tried the various powers of the distances and periods. Unfortunately an error of computation for some time concealed the discovery from him; but having resumed the subject, he at length found, on the 15th of May 1618 (and few days, as Mr Playfair has remarked, are more memorable in the annals of science), with all the delight which a great and important discovery gives rise to, that *the squares of the numbers which express the times of revolution are to one another as the cubes of those which express the mean distances of the planets from the sun.*

Theoretical Astronomy.

Third law of Kepler.

These three general laws, which are necessary consequences of the law of force varying directly as the masses and inversely as the squares of the distances, greatly facilitate the investigation of the orbit of a newly discovered planet, and may even be regarded as more accurate than the results obtained from any moderate number of observations, however exact. Thus, instead of having recourse to observation for the determination of the radius vector, which cannot be found by direct observation but with considerable difficulty, it is preferable to deduce it by means of the third law from the planet's periodic time, which can always be determined with great precision, and with much greater facility. They also afford a strong analogical proof of the annual motion of the earth. In fact, if we compute from the third law the periodic time of a body placed at the same distance from the sun as the earth is known to be, the result will give exactly the sidereal year. It is therefore certain that the earth obeys the same laws as the planets; and, when classed among them, the most perfect analogy pervades the whole system.

The periodic time of a planet may be determined by observing the interval which elapses between two consecutive passages through the same node. The retrograde movement of the nodes being, as we have seen, inconsiderable, the planet, in returning to its node, also returns to the same position very nearly with reference to the fixed stars, and therefore has in the interval completed a sidereal revolution. Hence the mean sidereal motion is known, and consequently, from the third law of Kepler, the planet's mean distance from the sun, the double of which is the transverse axis of the orbit. But the observation of the passages through the nodes not only gives the time of a sidereal revolution, but also approximate values of the eccentricity and the position of the line of the apsides; for, unless the orbit is circular, or the line of the apsides coincides with that of the nodes, the time the planet consumes in passing from the ascending to the descending node, or from ☊ to ☋, will be different from that in which it passes from ☋ to ☊; and, by a comparison of this difference with the theory of elliptic motion, it is easy to deduce the greatest difference between the true and mean anomalies, that is, the greatest equation of the centre, and thence the eccentricity. The method is exactly similar to that which has already been described in chap. ii. sect. 2.

But as these methods lead to results of no great accuracy, and as the passages through the nodes in the case of the distant planets occur only after considerable intervals of time, the astronomer requires some more accurate and expeditious means of determining the elements of an orbit; and three geocentric observations of the planet in any part of its orbit whatever are sufficient to determine these elements, when the nodes and inclination, mean motion and mean distance, are known. By the known

positions of the sun and planet relatively to the earth, the position of the planet with respect to the sun can be computed. Let then v, v', v'', represent three heliocentric longitudes of a planet, and π the longitude of the perihelion, all reduced to the plane of the orbit. The true anomalies corresponding to the three observations will consequently be $v-\pi$, $v'-\pi$, $v''-\pi$. Now, if, as in the series given in chapter ii. section 2, for the true anomaly in terms of the mean, we express the mean motion by n, and the time elapsed since the passage through the perihelion by t, the three corresponding mean anomalies will be respectively $n\,t$, $n\,t'$, $n\,t''$; and it will be observed, that although t is unknown, yet as $t'-t$ and $t''-t$ (the intervals between the first and the other two observations) are known, t' and t'' are both given in terms of t.

Omitting the square, and all the higher powers, of the eccentricity e, the series just referred to gives the three following equations,

$$n\,t = v - \pi - 2\,e\sin.(v-\pi)$$
$$n\,t' = v' - \pi - 2\,e\sin.(v'-\pi)$$
$$n\,t'' = v'' - \pi - 2\,e\sin.(v''-\pi)$$

from which we must deduce the three unknown quantities t, e, π, that is to say, the epoch of the planet's passage through the perihelion, the eccentricity, and the longitude of the perihelion. By subtracting the first of these equations from each of the other two, we obtain

$$n(t'-t) = v' - v - 2\,e\,[\sin.(v'-\pi) - \sin.(v-\pi)]$$
$$n(t''-t) = v'' - v - 2\,e\,[\sin.(v''-\pi) - \sin.(v-\pi)];$$

and if we assume

$$n(t'-t) - (v'-v) = a$$
$$n(t''-t) - (v''-v) = b$$

(a and b being thus known quantities), these two equations give us the two following,

$$a = -2\,e\,[\sin.(v'-\pi) - \sin.(v-\pi)]$$
$$b = -2\,e\,[\sin.(v''-\pi) - \sin.(v-\pi)];$$

whence, by division,

$$\frac{a}{b} = \frac{\sin.(v'-\pi) - \sin.(v-\pi)}{\sin.(v''-\pi) - \sin.(v-\pi)}$$

Now, the numerator of this fraction

$$= \sin.(v-\pi)\left\{\frac{\sin.(v'-\pi)}{\sin.(v-\pi)} - 1\right\}$$
$$= \sin.(v-\pi)\left\{\frac{\sin.v'\cos.\pi - \cos.v'\sin.\pi}{\sin.v\,\cos.\pi - \cos.v\sin.\pi} - 1\right\}$$
$$= \sin.(v-\pi)\left\{\frac{\sin.v' - \sin.v - \tan.\pi\,(\cos.v' - \cos.v)}{\sin.v - \cos.v\,\tan.\pi}\right\};$$

and, similarly, the denominator

$$= \sin.(v-\pi)\left\{\frac{\sin.v'' - \sin.v - \tan.\pi\,(\cos.v'' - \cos.v)}{\sin.v - \cos.v\,\tan.\pi}\right\};$$

therefore

$$\frac{a}{b} = \frac{\sin.v' - \sin.v - \tan.\pi\,(\cos.v' - \cos.v)}{\sin.v'' - \sin.v - \tan.\pi\,(\cos.v'' - \cos.v)};$$

whence

$$\tan.\pi = \frac{a(\sin.v'' - \sin.v) - b(\sin.v' - \sin.v)}{a(\cos.v'' - \cos.v) - b(\cos.v' - \cos.v)};$$

an equation which gives π, the longitude of the perihelion reduced to the orbit, the angles v, v', v'', being given by observation.

Having thus found π, and consequently $v-\pi$, $v''-\pi$, it is easy to determine the eccentricity e. From the equation

$$a = -2\,e\,[\sin.(v-\pi) - \sin.(v-\pi)]$$

we obtain

$$2e = -\frac{a}{\sin.(v'-\pi) - \sin.(v-\pi)};$$

a formula which may be rendered better adapted for logarithmic calculation by being put under the form

$$e = -\frac{a}{4\sin.\frac{v'-v}{2}\cdot\cos.\left(\frac{v'+v}{2} - \pi\right)}$$

By means of the values of e and $v-\pi$, which have now been found, we obtain t, the epoch of the passage of the planet through its perihelion, immediately from the equation

$$n\,t = v - \pi - 2\,e\sin.(v-\pi).$$

The only element which now remains undetermined is the radius vector, and this is given by the polar equation of the ellipse, viz.

$$r = \frac{a(1-e^2)}{1 + e\cos.(v-\pi)},$$

in which a represents the semi-axis major, or mean distance found by the third law of Kepler.

In this manner approximate values of the different elements are obtained, but no method can be proposed which will give them, without repeated corrections, so accurately as to accord with the precise observations of the present day; and the great object of the practical astronomer is to advance them gradually nearer and nearer to the truth. From the laws of Kepler applied to a few observations, formulæ are constructed which represent the mean values of the elliptic elements nearly; every successive observation gives a geocentric latitude and longitude; and by comparing these with the corresponding latitude and longitude computed from the formulæ, equations of condition are obtained, by means of which the formulæ are corrected and rendered still more exact. New observations give new equations of condition, to be joined with the former; and after a great number of such equations have been obtained, geometry teaches us how to combine them so that each may have its just influence in the determination of the final result. Thus the tables are gradually approximated to perfection, or to such a state that they differ only insensibly from the mean of a great number of observations.

But the great difficulty of obtaining an exact conformity between observation and the results of computation arises from the circumstance that the different elements of the orbits have no fixed values, but are incessantly though slowly varying, in consequence of the mutual disturbances which the planets occasion to the motions of each other. If the planets had no mutual attraction, and obeyed only the central force of the sun, the problem of determining the different circumstances of their motion would be one of easy solution, and each of them would accurately describe an ellipse on the plane of its orbit, according to the laws of Kepler. In consequence, however, of their mutual attraction, every planet is compelled to deviate more or less from its ellipse; so that when the matter is viewed with mathematical precision, the laws of Kepler belong only to an ideal system, and have no actual existence in nature. It is in the determination of the amount of these effects of perturbation, and the secular variations they give rise to, that the most profound and intricate theories of physical astronomy find their application; for it is from theory alone that we can derive any knowledge of the laws and periods of changes which are completed only after many hundreds or thousands of years. The planets whose motions are most disturbed by their mutual attractions are Jupiter and Saturn; and even with respect to them, observation, although it makes

Theoretical Astronomy.

known the existence of inequalities, can neither detect their laws nor assign their periods. The only elements which are exempted from secular changes occasioned by the perturbing forces are the greater axes of the orbits, and the mean motions depending on them according to the third law of Kepler. The eccentricities of the orbits vary slowly. With regard to Mercury, Mars, and Jupiter, those elements are at the present time increasing; in the cases of Venus, the Earth, Saturn, and Uranus, they are diminishing. The perihelia are also gradually shifting their places on the planes of the orbits. These motions are direct in the case of all the planets excepting Venus, the perihelion of whose orbit, when referred to the fixed stars, moves in a direction contrary to that of the signs.

Theoretical Astronomy.

The following table exhibits the mean motions of the planets, and the elements and positions of their ellipses on the planes of their orbits, at the commencement of the year 1801. For the four new planets the epoch is 1820.

3. *Of the real Dimensions of the Planetary Orbits, and the Transits of Venus and Mercury over the Sun's Disk.*—In what has hitherto been said respecting the mean distances of the planets from the sun, those distances have been estimated in parts of the semi-axis major of the earth's orbit; a convenient scale, which enables us to form a very precise idea of the relative dimensions of the several orbits, and likewise serves to express their absolute dimensions, provided we can determine the distance between the sun and the earth in terms of any measure with which we are familiar. It is evident, indeed, in consequence of the relation that subsists between the mean distances and mean motions, that it is only necessary to determine the mean distance of any one of the planets from the sun, in order to determine the mean distances of all the others, and assign the dimensions of the whole solar system. Now there are various ways of determining the sun's distance from the earth in terms of the earth's semidiameter. The distance of a planet from the sun may likewise be obtained if we can find the means of measuring its distance from the earth at any epoch; for the geocentric positions of the sun and the planet being known from the theory of their motions, the radius vector of the orbit, or planet's distance from the sun at that epoch, may be found by a simple trigonometrical computation. To determine the distance of a planet from the earth, it might seem only necessary to determine its horizontal parallax; but in general the parallaxes of the planets are quantities by far too small to be directly observed. That of Mars, however, becomes very appreciable in particular circumstances, that is to say, when Mars is in opposition with the sun, and at the same time near the perihelion of his orbit. Thus, in the year 1751, on the 6th of October, that planet, being near his opposition, was observed at the same instant of time by Lacaille at the Cape of Good Hope, and by Wargentin at Stockholm; and the horizontal parallax deduced from the two observations, in the manner explained in chap. i. sect. 2, was found to amount to 24″·6. Now the distance of the planet being equal to unity divided by the sine of the horizontal parallax, the distance of Mars from the earth at the time of the observation was consequently

$$1 \div \frac{24''\cdot6 \times 3\cdot1416}{180^\circ \times 60 \times 60} = \frac{648000}{77\cdot28} = 8381 \text{ terrestrial radii.}$$

But the distance of Mars from the earth at that time, as computed from the theory of his elliptic motion, was 0·435 parts of the radius of the earth's orbit; consequently the whole length of that radius is $\frac{8381}{0\cdot435} = 19226$ semidiameters of the earth. Hence the distance of Mars from the sun = 19226 + 8381 = 27607 semidiameters of the earth. It will be remarked that these numbers are only approximative, our present object being to explain the method, and not to determine the exact quantities.

But besides the inconvenience attending the determination of a planet's distance by this method, which requires observations to be made simultaneously on opposite sides of the earth, the method is in itself liable to great uncertainty. The error of a result is always in a certain proportion to the error of observation, and in the present case a very large quantity is to be determined from a very small one; hence a very slight error of observation will occasion a very erroneous result in the computation of the mean distance. It would be difficult in a single observation of this nature to answer for an error of 2″; but here 2″ is a twelfth part of the whole parallax; consequently an uncertainty amounting to a twelfth part affects the mean distance.

A much more accurate method of determining the sun's distance, and thence the dimensions of the planetary orbits, is afforded, though rarely, by the transits of Venus over the sun's disk. When Venus is at her inferior conjunction, and at the same time very near her node, her body will be projected on the disk of the sun; and through the effect of her proper motion, combined with that of the earth, she will appear as a dark spot passing over the disk, and describing a chord which will be seen under different aspects by spectators placed at different points on the earth, because, by reason of the parallax, they refer the planet to different points on the solar disk. The position of the spectator not only occasions a difference in the apparent path described by the planet, but has also a very sensible influence on the duration of the transit, in consequence of which the parallaxes both of Venus and the sun can be determined with great exactness. In order to illustrate this, let E (fig. 73) represent the earth, V Venus, and S the sun. An observer placed at E, the centre of the earth, would see Venus in the di-

Theoretical Astronomy.

rection of the visual ray EV: she would consequently appear to him projected on the sun's disk at S, and in her successive positions would appear to describe the line DS. Other observers placed at O′ and O″ on the earth's surface would see the planet at V′ and V″: to the first she would appear to describe the chord D′V′, and to the second D″V″. This is a necessary result of the difference of the parallaxes of Venus and the sun; and as the chords D′V′, D″V″ differ in length according as they are more or less remote from the centre of the disk, the duration of the transit will be longer or shorter according to the situation of the observer and the geocentric latitude of the planet. If by reason of the relative parallax the time of a transit is longer than the true time in one hemisphere, it will be shorter in the opposite; and hence the difference of the times (which may be observed with great accuracy) at places having very different latitudes may serve to determine the relative parallax, or the difference between the parallax of Venus and that of the sun. But the parallaxes are reciprocally proportional to the distances; and the ratio of the distances being known, therefore the ratio of the parallaxes is also known; and having thus the ratio and the difference of the two parallaxes, it is easy to compute the separate amount of each.

This particular application of the transits of Venus to the determination of the sun's distance was first pointed out by Dr Halley, when he announced the transits of 1761 and 1769. Kepler had before announced the occurrence of a transit, but he regarded it only as a curious, and till that time unobserved, phenomenon.

The transit of Venus which occurred in 1769 was anxiously expected by astronomers, and observed in many different parts of the world. The result of the whole of the observations renders it extremely probable that the parallax of the sun is included within the limits of 8″·5 and 8″·7. The mean 8″·6 has been adopted by Delambre and Lalande. From the following table, computed from the different observations, and published by Delambre in the second volume of his *Astronomie*, p. 505, an idea may be formed of its probable accuracy. Delambre, indeed, remarks that the sun's parallax is now sufficiently well known for all the practical purposes of astronomy.

Having once obtained the value of the solar parallax, it is easy to deduce the sun's distance, and consequently the dimensions of all the planetary orbits. For this purpose we have

Theoretical Astronomy.

sin. 8″·6 : 1 :: radius of earth : sun's distance;

that is, on reducing the radius of a circle to seconds,

$$\text{sun's distance} = \frac{\text{earth's radius}}{8''\cdot6 \times \sin. 1''} = 23984 \text{ terrestrial radii.}$$

Now, if we assume the semidiameter of the earth to be 4000 miles in round numbers, the distance of the sun, or radius of the earth's orbit, will consequently be 23984×4000=95936000 miles approximately.

By means of this value the mean distances of the planets from the sun, which in the table given above were expressed in terms of the mean distance of the earth, may be converted into miles. The following are the results in round numbers.

Planet.	Mean Distance from the Sun in Miles.
Mercury	37,000,000
Venus	68,000,000
Earth	95,000,000
Mars	142,000,000
Ceres	262,000,000
Jupiter	485,000,000
Saturn	890,000,000
Uranus	1,800,000,000

Periodic recurrence of the transits.

The transits of Venus being phenomena of great importance, in consequence of their practical application to the problem of the sun's distance, it becomes interesting to determine the periods at which they successively occur. It is evident that, by reason of the inclination of the orbit, they can only take place when Venus is very near one of her nodes. Two conditions must therefore be satisfied: Venus must be within a short distance of her node, and at the same time in her inferior conjunction. Now, the interval between two successive conjunctions, that is, the period of a synodic revolution, is easily deduced from the sidereal revolutions of the planet and the earth. Thus, generally, let A and B be two planets, T and t the times of their sidereal revolutions respectively, and suppose T to be greater than t. In the time T, A describes a complete circumference, therefore $T : t :: 1 : \frac{t}{T}$ = part of a circumference described by A in the time t. But during the same time t, B describes a whole circumference; therefore $1 - \frac{t}{T}$ is what B gains on A in the time t. But the successive conjunctions will always take place when B has gained a whole circumference; therefore, denoting by S the interval between two successive conjunctions, we have $1 - \frac{t}{T} : 1 :: t : S$, whence $S = \frac{Tt}{T-t}$.

From this simple formula the synodic revolution of any of the planets is found by substituting for T and t the times of the sidereal revolutions of the earth and planet. Suppose, for example, we wish to find the time of a synodic revolution of Mercury. In this case T=365·256 days, and t = 87·969 days; consequently $T - t$ = 277·287, and

$$S = \frac{365\cdot256 \times 87\cdot969}{277\cdot287} = 115\cdot877 \text{ days,}$$

which, therefore, is the time of a synodic revolution of Mercury.

In the case of Venus we have t = 224·700, whence $T - t$ = 365·256 − 224·700 = 140·556, and consequently

$$S = \frac{365\cdot256 \times 224\cdot700}{140\cdot556} = 583\cdot93 \text{ days;}$$

which is the period of her synodic revolution.

Theoretical Astronomy.

Let us next attend to the other condition which must be satisfied before a transit can take place, namely, that the planet has returned to its node as well as to its inferior conjunction. If we represent by m the number of revolutions of the earth in the required period, and by n the number of synodic revolutions of the planet in the same time, it is evident that we shall have $m\mathrm{T} = \frac{n\mathrm{T}t}{\mathrm{T}-t}$, whence $\frac{m}{n} = \frac{t}{\mathrm{T}-t}$. In the case of Mercury, therefore, $\frac{m}{n} = \frac{87969}{277287}$; that is to say, after 87969 years, in the course of which Mercury will have been 277287 times in conjunction, the earth and Mercury will be again in conjunction, occupying the same points of their orbits as at the commencement of the period, supposing the nodes fixed. But periods of such enormous length are of no practical use: it is necessary to find an approximating ratio expressed by smaller numbers. For this purpose it is convenient to have recourse to the method of continued fractions, from which the following series is obtained:—

$$\frac{87969}{277287} = \frac{1}{3} + \frac{1}{6} + \frac{1}{11} + \frac{1}{1} + \frac{1998}{5691}.$$

Here the first approximating fraction is $\frac{1}{3}$, which denotes that in one year, during which there will happen three synodic periods, Mercury will not be very far from his conjunction, nor from the same point of his orbit in which he was at the commencement of that time. The next approximation is $\frac{1}{3} + \frac{1}{6} = \frac{6}{19}$, showing that after six years, during which there will have been 19 conjunctions, Mercury will be again nearly in conjunction at the same point of his orbit. By continuing the process we obtain the following series of fractions, each approaching nearer to $\frac{87969}{277287}$, namely,

$$\frac{1}{3}, \frac{6}{19}, \frac{7}{22}, \frac{13}{41}, \frac{33}{104}, \frac{46}{145}, \text{ \&c.}$$

of which the numerators express the number of years, and the denominators the corresponding number of synodic revolutions.

Approximative fractions might be found in the same manner to express the ratio of the number of revolutions of Mercury to those of the earth, or of $\frac{t}{\mathrm{T}}$; but it is unnecessary to have recourse again to division, inasmuch as they are easily obtained from the above. For example, since the fraction $\frac{1}{3}$ denotes that Mercury has *gained* three revolutions on the earth in one year, it is evident that he must have completed $3+1=4$ revolutions. In the same way, in six years Mercury gains 19 on the earth, or completes $19+6=25$. Hence, in the series required the numerators of the fractions will continue the same as in the series above, while the denominators will be the sums of the terms of the corresponding fractions. The new series will therefore be

$$\frac{1}{4}, \frac{6}{25}, \frac{7}{29}, \frac{13}{54}, \frac{33}{137}, \frac{46}{191}, \text{ \&c.}$$

the numerators being the number of years, and the denominators the corresponding periods of Mercury.

Applying to the case of Venus and the earth the formula $\frac{m}{n} = \frac{t}{\mathrm{T}-t}$, we shall have $t = 224{\cdot}7008$, $\mathrm{T}-t = 365{\cdot}2563 - 224{\cdot}7008 = 140{\cdot}5555$; therefore $\frac{m}{n} = \frac{2247008}{1405555}$.

Theoretical Astronomy.

The series of fractions approximating to this ratio, obtained in the manner indicated above, is

$$\frac{1}{1}, \frac{2}{1}, \frac{3}{2}, \frac{8}{5}, \frac{227}{142}, \frac{235}{147}, \frac{243}{152}, \text{ \&c.}$$

the numerators of which, as before, express the years, and the denominators the synodic periods. Taking the fourth fraction of the series, it appears that after eight years, in which there are five synodic periods, Venus will again occupy nearly the same position with respect to the earth and the nodes of her orbit. This will take place more nearly after 227 years, and more nearly still after 235; consequently, 235 years after a transit has taken place, the occurrence of another may be expected with great probability. The alteration, however, which takes place in the position of the line of the nodes, which in the preceding computations we have regarded as fixed, renders the numbers a little uncertain.

Since Venus returns to her conjunction at nearly the same point of her orbit after eight years, it may happen, and sometimes indeed actually does happen, that a transit will take place in about eight years after the occurrence of a former one. But in that time the latitude of Venus, in consequence of the inclination of her orbit, undergoes a variation amounting to 20′ or 24′; in sixteen years the change of latitude increases to 40′ or 48′, which is considerably greater than the diameter of the sun. It cannot happen, therefore, that three transits will take place within sixteen years. From the above series of fractions we might infer that another could not take place before 227 years; but that series was obtained on the supposition that the transits only happen when Venus returns to the *same* node; and it is evident that they may equally occur when the planet is near the other node, and consequently after an interval of half the length of the former, or 113 years. If, at the occurrence of the first transit, Venus has passed her node, the next will happen eight years sooner; or, if she has not reached the node, eight years later. Hence, after two transits have occurred within eight years, another cannot be expected before 105, 113, or 121 years, that is, 113 ± 8 years. But these periods sometimes fail: that of 235 brings about the phenomenon with greater certainty, and 243 (which is the double of 121) is the surest of all. The periods of 235 and 251 are that of 243 diminished or augmented by 8. The whole calculation, therefore, reduces itself to periods of 121 and ± 8 years. The last transits took place in 1761 and 1769; the next will not happen till the years 1874 and 1882; and thus the infrequency of these phenomena adds to the interest they derive from their real importance.

Delambre has given a list of all the transits of Venus for a period of 2000 years, from which the following is extracted. (*Astronomie*, tome ii. p. 473.)

Year.	Month.	Mean Time (at Paris) of Conjunction.	Node.

Theoretical Astronomy.

SECT. III.—*Of the Physical Constitution of the Planets, their Magnitude, Rotation, and other remarkable objects.*

Mercury.

Mercury is a small body, but emits a very bright white light, though, by reason of his always keeping near the sun, he is seldom to be seen; and when he does make his appearance, his return to the sun is so rapid, that he can only be discerned for a short space of time. Delambre was able to observe him only twice with the naked eye.

Mercury is about 3140 English miles in diameter, and his mean distance from the sun about 37 millions of miles. On account of his smallness and brilliancy it is extremely difficult to find any spot on his disk so distinctly marked as to afford the means of determining his rotation. Besides, by reason of his proximity to the sun, an observation of a spot, if made in the evening, can scarcely be well begun before the planet sets; or, if in the morning, before the increasing twilight renders the spot invisible. Hence it is only possible to observe daily a very small arc of a small circle; and if the spot re-appears on the succeeding day, it is doubtful whether the arc which it has passed over exhibits the whole motion, or if one or more circumferences ought to be added. By an attentive observation of the variations of the phases of Mercury, Schroeter has, however, remarked that he revolves about his axis in the space of 24 hours 5 minutes 30 seconds. M. Harding discovered in 1801 an obscure streak on the southern hemisphere of the planet, the observations of which, together with those of a spot discovered by Schroeter, gave the same period of rotation. The results of Schroeter's researches on Mercury may be summed up as follows: 1*st*, The apparent diameter of Mercury at his mean distance is 6″·02; 2*d*, His form is spherical, exhibiting no sensible compression; 3*d*, His equator is very considerably inclined to his orbit, and the differences of his days and seasons must consequently be very great; 4*th*, There are mountains on his surface which cast very long shadows, and of which the height bears a greater proportion to the diameter of the planet than those of the Earth, the Moon, or even of Venus. The height of Chimboraço is $\frac{1}{1017}$ of the radius of the earth; one of the mountains in the moon has been estimated at $\frac{1}{214}$ of her radius; the highest in Venus at $\frac{1}{144}$; and one in Mercury at $\frac{1}{120}$. The highest mountains are in the southern hemisphere, which is also the case in respect of the Earth and Venus. There are no observations to prove decisively whether Mercury is surrounded by an atmosphere.

Venus.

Venus, the most beautiful object in the heavens, is about 7700 English miles in diameter, and placed at the distance of 68 millions of miles from the sun. Although the oscillations of this planet are considerably greater than those of Mercury, and she is seldom invisible, yet on account of the uniform brilliancy of her disk, it is extremely difficult to ascertain the period of her rotation. Dominic Cassini, after having long fruitlessly attempted to discover any object on her surface so well defined as to enable him to follow its motions, at length, in 1667, perceived a bright part, distant from the southern horn a little more than a fourth part of the diameter of the disk, and near the eastern edge. By continuing his observations on this spot, Cassini concluded the rotation of Venus to be performed in about 23 hours; but he does not seem to have considered this conclusion as deserving of much confidence. In the year 1726 Bianchini, an Italian astronomer, made a number of similar observations for the same purpose, from which he inferred that the rotation of the planet is performed in 24 days 8 hours. The younger Cassini has shown, however, that the observations of Bianchini, as well as those of his father, could be explained by a rotation of 23 hours and 21 or 22 minutes, whereas the rotation of 24 days 8 hours cannot be reconciled with the appearances observed by the elder Cassini. The determination of Cassini was regarded by astronomers as the more probable of the two, particularly as Bianchini was not able to make his observations in a connected manner, on account that a neighbouring building intercepted his view of the planet, [illegible] aim to transport his telescope to a different situation. The question of the rotation of Venus was finally settled by Schroeter, who found it to be performed in 23 hours 21 minutes 19 seconds. Each of the three observers found the inclination of the axis of rotation to the axis of the ecliptic to be about 75°. Some doubt, however, still exists with respect to the value of this element.

Theoretical Astronomy

Schroeter's observations on this planet were principally directed to a mountain situated near the southern horn. The line which joins the extremities of the horns is always a diameter; and the horns of the crescent of a perfect sphere ought to be sharp and pointed. Schroeter remarked that this was not always the case with regard to the horns of Mercury and Venus. The northern horn of the latter always preserved the pointed form, but the southern occasionally appeared rounded or obtuse,—a circumstance which indicated that the shadow of a mountain covered the part B*o* (fig. 74), so that the line joining the extremities of the horns appeared to be A*o*, and not AB (the diameter of the circular disk); but at *d*, beyond *o*B, he remarked a luminous point, which he supposed to be the summit of another mountain, illuminated by the sun after he had ceased to be visible to the rest of that hemisphere. Now, in order that the horn of the crescent may appear obtuse in consequence of the shadow of a mountain falling upon it, and another mountain *d* present a luminous point, the two mountains must be at the same time both at the edge of the disk and on the line separating the dark from the enlightened part of the planet. But this position cannot be of long continuance; for the rotation will cause *d* to rise into the enlightened part, or sink into the dark hemisphere, and in either case the mountain will cease to be visible. If, however, the rotation is completed in 23 hours 21 min., the mountain *d* will appear 39 min. sooner than it did on the previous day; for in the course of a day the boundary of light and darkness will hardly have shifted its position on the surface of the planet through the effects of the orbital motion. Hence it is possible to obtain several consecutive observations, from which an approximate value of the period may be found; and this being once obtained, it may be rendered still more exact by observations separated from each other by a longer interval. Thus Schroeter found that an interval of 20 days 11 hours 15 min. between two apparitions of the mountain being divided by 23 hours 21 min., gave 21·04 revolutions. That intervals of 121 days 14 hours 25 min., 142 days 1 hour 40 min., 155 days 18 hours 11 min., divided each by 23 hours 21 min., gave 125·01, 146·02, 160·09 revolutions respectively. All these comparisons prove that the revolution of 23 hours 21 min. is somewhat too short. They ought to have given 21, 125, 146, and 160 revolutions exactly, supposing the observations to have been perfectly accurate. On dividing the intervals by 21, 125, 146, and 160 respectively, the quotients will be each the time of a revolution very nearly; and by taking a mean among the whole, the most pro-

Theoretical Astronomy.

table result at least will be obtained. In this manner Schroeter found the period of rotation already stated, namely, 23 hours 21 min. 19 sec.

Since the time of rotation of Mercury and Venus is nearly equal to that of the earth, the compression of these planets at the poles, which results from the centrifugal force, ought also to be nearly in the same proportion. But at the distance of the earth the compression must be imperceptible even in the case of Venus; for, supposing it to amount to $\frac{1}{300}$, the difference between the radius of her poles and that of her equator would only amount to a tenth of a second as seen from the earth.

Atmosphere of Venus.

During the transits of Venus over the sun's disk in 1761 and 1769 a sort of penumbral light was observed round the planet by several astronomers, which was occasioned, without doubt, by the refractive powers of her atmosphere. Wargentin remarked that the limb of Venus which had gone off the sun showed itself with a faint light during almost the whole time of emersion. Bergman, who observed the transit of 1761 at Upsal, says that at the ingress the part which had not come upon the sun was visible, though dark, and surrounded by a crescent of faint light, as in fig. 75; but this appearance was much more remarkable at the egress: for as soon as any part of the planet had disengaged itself from the sun's disk, that part was visible with a like crescent, but brighter (fig. 76). As more of the planet's disk disengaged itself from that of the sun, the part of the crescent farthest from the sun grew fainter, and vanished, until at last only the horns could be seen, as in fig. 77. The total immersion and emersion were not instantaneous; but as two drops of water, when about to separate, form a ligament between them, so there was a dark shade stretched out between Venus and the sun, as in fig. 78; and when this ligament broke, the planet seemed to have got about an eighth part of her diameter from the limb of the sun (fig. 79). The numerous accounts of the two transits which have been published abound with analogous observations, indicating the existence of an atmosphere of considerable height and density. Schroeter calculated that its horizontal refraction must amount to 30′ 34″, differing little from that of the terrestrial atmosphere. A twilight which he perceived on the cusps afforded him the data from which he deduced this conclusion.

Cassini and Montaigne imagined that they had observed a satellite accompanying Venus; but this appears to have been an optical illusion arising from the strong light of the planet reflected back from the convex surface of the eye upon the eye-glass of the telescope, and thence reflected a second time back to the eye. This hypothesis at least will explain the appearances which they have described; and although astronomers have sought for this pretended satellite with great care, they have neither observed it on the sun during the transits of Venus in 1761 and 1769, nor in any other part of her orbit.

Mars.

After Venus, Mars is the planet whose orbit is nearest to the earth. His diameter is about one half, and his volume only about one sixth part of that of our globe. He is of a dusky reddish colour, by reason of which he is easily recognised in the heavens. His mean distance from the sun is about 142 millions of miles.

The rotation of Mars was suspected before the year 1643 by Fontana, a Neapolitan astronomer; but it was reserved for Cassini to demonstrate its existence and assign its period. Cassini began to observe the spots on the surface of Mars at Bologna in 1666; and after having continued his observations for a month, he found they returned to the same situation in 24 hours and 40 min. The planet was observed by some astronomers at Rome with longer telescopes; but they assigned to it a rotation of 13 hours only. This, however, was afterwards shown by Cassini to have arisen from their not distinguishing between the opposite sides of the planet, which, it seems, have spots pretty much alike. He made further observations on the spots of this planet in 1670; which confirmed his former conclusion respecting the time of rotation. The spots were again observed in subsequent oppositions, particularly for several days in 1704 by Maraldi, who took notice that they were not always well defined, and that they not only changed their shape frequently in the interval between two oppositions, but even in the space of a month. Some of them, however, continued of the same form long enough to allow the time of the planet's rotation to be determined. Among these there appeared that year an oblong spot, resembling one of the belts of Jupiter when broken. It did not reach quite round the body of the planet; but had, not far from the middle of it, a small protuberance towards the north, so well defined that Maraldi was thereby enabled to fix the period of its revolution at 24 hours 39 min., only one minute less than what Cassini had determined it to be.

Theoretical Astronomy.

The near approach of Mars to the earth in 1719 afforded an excellent opportunity of observing him, as he was then within $2\frac{1}{2}°$ of his perihelion, and at the same time in opposition to the sun. His apparent magnitude and brightness were thus so much increased, that he was by the vulgar taken for a new star. His appearance at that time, as seen by Maraldi through a telescope of 34 feet long, is represented in fig. 80. There was then a long belt that reached half-way round, to the end of which another shorter belt was joined, forming an obtuse angle with the former, as in fig. 81. This angular point was observed on the 19th and 20th of August, a little to the east of the middle of the disk; and 37 days after, on the 25th and 26th of September, it returned to the same situation. This interval, divided by 36, the number of revolutions contained in it, gives 24 hours 40 minutes for the period of one revolution; a result which was verified by another spot of a triangular shape, one angle whereof was towards the north pole, and the base towards the south, and which on the 5th and 6th of August appeared as in fig. 82. After 72 revolutions it returned to the same situation on the 16th and 17th of October. Some of the belts of this planet are said to be parallel to his equator; but that seen by Maraldi was very much inclined to it.

Bright spots about the poles of Mars.

Besides these dark spots on the surface of Mars, astronomers had noticed that a segment of his globe about the south pole exceeded the rest of his disk so much in brightness, that it appeared to project as if it were the segment of a larger globe. Maraldi informs us that this bright spot had been taken notice of for 60 years, and was more permanent than the other spots on the planet. One part of it is brighter than the rest, and the least bright part is subject to great changes, and has sometimes disappeared.

A similar though less remarkable brightness about the north pole of Mars was also sometimes observed, the existence of which has been confirmed by Sir W. Herschel, who examined the planet with telescopes of much greater power than any former astronomer ever was in possession of. A very full account of Herschel's observations on this planet is given in the 74th volume of the *Philosophical Transactions*. Some of the remarkable appearances there described are represented in fig. 83–88. The magnifying powers he used were sometimes as high

Herschel's account of these spots.

as 932; and with this the south polar spot was found to be 41″′ in diameter. Fig. 96 shows the connection of the other figures marked 89, 90, 91, 92, 93, 94, 95, which complete the whole equatorial succession of spots on the disk of the planet. "The centre of the circle," Herschel observes, "marked 90, is placed on the circumference of the inner circle, by making its distance from the circle, marked 92, answer to the interval of time between the two observations, properly calculated and reduced to sidereal measure. The same is done with regard to the circles marked 91, 92, &c.; and it will be found by placing any one of these connected circles in such a manner as to have its contents in a similar situation with the figures in the single representation, which are marked with the same number, that there is a sufficient resemblance between them; though some allowance must be made for the distortions occasioned by this kind of projection."

From these observations Herschel concluded that the diurnal rotation of Mars is accomplished in 24 hours 39 minutes 21⅔ seconds; that his equator is inclined to his orbit in an angle of 28° 42′, and his axis of rotation to the axis of the ecliptic in an angle of 30° 18′. Hence the time of rotation and the seasons of this planet are little different from those of the earth.

The bright appearance so remarkable about the poles of Mars is ascribed by Herschel to the reflection of light from mountains of ice and snow accumulated in those regions. "The analogy between Mars and the earth," says he, "is perhaps by far the greatest in the whole solar system. Their diurnal motion is nearly the same, the obliquity of their respective ecliptics not very different; of all the superior planets, the distance of Mars from the sun is by far the nearest alike to that of the earth; nor will the length of the Martial year appear very different from what we enjoy, when compared to the surprising duration of the years of Jupiter, Saturn, and the Georgium Sidus. If we then find that the globe we inhabit has its polar region frozen and covered with mountains of ice and snow, that only partly melt when alternately exposed to the sun, I may well be permitted to surmise, that the same causes may probably have the same effect on the globe of Mars; that the bright polar spots are owing to the vivid reflection of light from frozen regions; and that the reduction of those spots is to be ascribed to their being exposed to the sun."

Since the discovery of the flattened form of the earth, it was to be presumed that the rotation of the other planets would produce a similar effect on their figures, and this supposition has been fully confirmed by observation. The time of the rotation of Mars is nearly equal to that of the earth, but his diameter being only about half that of the earth, the velocity of a point on his equator is consequently only half as great as that of a point on the earth's equator: hence we might expect that the deviation of his figure from a perfect sphere would be much less considerable. The contrary, however, appears to be the case; and his compression seems to be much greater than that of the earth. According to Herschel, the ratio of his equatorial and polar axes is 103 to 98. Schroeter estimates the same ratio to be that of 81 to 80. This remarkable compression at the poles of Mars arises in all probability from considerable variations of density in the different parts of his globe.

Atmosphere of Mars.

It has been commonly related by astronomers, that the atmosphere of this planet is possessed of such strong refractive powers as to render invisible the small fixed stars near which it passes. Dr Smith relates an observation of Cassini, in which a star in the water of Aquarius, at the distance of six minutes from the disk of Mars, became so faint before its occultation, that it could not be seen by the naked eye, nor even with a three feet telescope. This would indicate an atmosphere of a very extraordinary size and density; but the following observations of Herschel seem to show that it is of much smaller dimensions. "1783, Oct. 26th. There are two small stars preceding Mars, of different sizes; with 460 they appear both dusky red, and are pretty unequal; with 218 they appear considerably unequal. The distance from Mars of the nearest, which is also the largest, with 227, measured 3′ 26″ 20″′. Some time after, the same evening, the distance was 3′ 8″ 55″′, Mars being retrograde. Both of them were seen very distinctly. They were viewed with a new 20 feet reflector, and appeared very bright. October 27th: the small star is not quite so bright in proportion to the large one as it was last night, being a good deal nearer to Mars, which is now on the side of the small star; but when the planet was drawn aside, or out of view, it appeared as plainly as usual. The distance of the small star was 2′ 5″ 25″′. The largest of the two stars," adds he, "on which the above observations were made, cannot exceed the 12th, and the smallest the 13th or 14th magnitude; and I have no reason to suppose that they were any otherwise affected by the approach of Mars, than what the brightness of its superior light may account for. From other phenomena it appears, however, that this planet is not without a considerable atmosphere; for, besides the permanent spots on its surface, I have often noticed occasional changes of partial bright belts, and also once a darkish one in a pretty high latitude; and these alterations we can hardly ascribe to any other cause than the variable disposition of clouds and vapours floating in the atmosphere of the planet."

Ceres, Pallas, Juno, and Vesta.

The commencement of the present century was rendered remarkable in the annals of astronomy by the discovery of four new planets circulating between Mars and Jupiter. Kepler, from some analogy which he found to subsist among the distances of the planets from the sun, had long before suspected the existence of one at this distance; and his conjecture was rendered more probable by the discovery of Uranus, with regard to which the analogy of the other planets is observed. So strongly, indeed, were astronomers impressed with the idea that a planet would be found between Mars and Jupiter, that, in the hope of discovering it, Baron Zach formed an association of 24 observers, who divided the sky into as many zones, and undertook each to explore one carefully. A fortunate accident anticipated a discovery which might have required years of toil. An error in the catalogue of Wollaston, who had laid down a star in a position in which it is not to be found, engaged Piazzi, the superintendent of the observatory at Palermo, to observe for several successive days all the small stars in the neighbourhood of the place indicated. On the first day of the present century, the 1st of January 1801, he observed a small star in Taurus, which, on the day following, appeared to have changed its place. On the 3d he repeated his observation, and was then satisfied that it had a diurnal motion of about 4′ in right ascension, and 3′½ in declination towards the north pole. He continued to observe it till the 23d, when he communicated his discovery to MM. Bode and Oriani, giving them the positions of the star on the 1st and 23d, and only adding, that between the 11th and 13th its motion had changed from retrograde to direct. Before the communication reached them, however, the planet was lost in the sun's rays; and, owing to its ex-

Theoretical Astronomy.

treme smallness. the difficulty of finding it after its emergence was so great, that it was not again seen till the 31st of the following December, when it was detected by Zach. In this was recognised the planet which Kepler had suspected to circulate between Mars and Jupiter. Piazzi, in honour of Sicily, gave it the name of the tutelary goddess of that country, *Ceres;* and her emblem, the sickle, ☽, has been adopted as its appropriate symbol.

Ceres is of a reddish colour, and appears to be about the size of a star of the eighth magnitude. The eccentricity of her orbit is somewhat greater than that of Mercury; and its inclination to the ecliptic greater than that of any of the old planets. The distance of Ceres from the sun is about 3·2 times that of the earth, or nearly 270 millions of miles. Schroeter found her apparent diameter to be 2″, corresponding to about 1624 miles; but Herschel reduced this measurement to 0″·5, which would indicate a diameter of about 160 miles. The nebulosity which surrounds the planet renders it almost impossible to distinguish the true disk; and hence arises the great discrepancy between the above estimates of its magnitude. From a great number of observations, Schroeter inferred that Ceres has a dense atmosphere, rising to the height of no less than 675 English miles above the planet, and subject to numerous changes. On this account he conceives that there is little chance of discovering the period of its rotation.

Discovery of Pallas.

The difficulty of finding Ceres induced Dr Olbers of Bremen to examine with particular care the configurations of all the small stars situated near her geocentric path. On the 28th of March 1802 he observed a star of the seventh magnitude, which formed an equilateral triangle with the stars 20 and 191 of Virgo in Bode's catalogue. He was certain that he had never seen a star in that place before, and at first imagined it might be one of those which are subject to periodical changes of brilliancy; but after examining it for two hours, he remarked that its right ascension was diminishing, while its northern declination continued to augment nearly in the same manner as had been the case with Ceres when that planet was first seen by him in almost the same position. On the following day he found its right ascension had diminished 10′, while its northern declination had increased 20′. From observations continued during a month, M. Gauss calculated an elliptic orbit, the eccentricity of which amounted to ·24764, much greater than that of any of the other planets. He also found its inclination to be 34° 39′, exceeding the aggregate inclinations of all the other planetary orbits; and its mean distance 2·770552, almost the same as that of Ceres. On account of these three circumstances, the new planet, otherwise of little importance, became the most singular in the whole system. One planet had been suspected to exist between Mars and Jupiter, and two were now discovered. The great inclination of the last rendered it necessary to enlarge the boundaries of the zodiac; but the extent of the zodiac is entirely arbitrary, and had been limited by the extreme latitudes of Venus. There is no reason, as Delambre remarks, why it may not be extended even to the poles. Dr Olbers gave the new planet the name of Pallas, choosing for its symbol the lance, ⚴, the attribute of Minerva.

The most surprising circumstance connected with the discovery of Pallas was the existence of two planets at nearly the same distance from the sun, and apparently having a common node. On account of this singularity Dr Olbers was led to conjecture that Ceres and Pallas are only fragments of a larger planet, which had formerly circulated at the same distance, and been shattered by some internal convulsion. Lagrange made this hypothesis the subject of an ingenious memoir, in which he determined the explosive force necessary to detach a fragment from a planet with a velocity that would cause it to describe the orbit of a comet. He found that a fragment detached from the earth in this manner, with a velocity equal to 121 times that of a cannon-ball, would become a direct comet; and if with a velocity equal to 156 times that of a cannon-ball, its motion would be retrograde. For other planets the velocity must be $\frac{121 \text{ or } 156}{\sqrt{\text{mean distance}}}$, and consequently less as the mean distance of the planet from the sun is greater. A smaller velocity would be required to cause the detached fragment to move in an elliptic orbit; and with regard to the four small planets we are now considering, an explosive force less than twenty times that of a cannon-ball would have sufficed to detach them from a primitive planet, and cause them to describe ellipses similar to their actual orbits. This hypothesis served also to explain the great eccentricities and inclinations by which these planets are distinguished from the others belonging to the system; for it is evident that the explosive force must have projected the different fragments in all directions, and with different velocities. It followed also, that other fragments of the original planet might probably exist, revolving in orbits which, however they might differ in respect of inclination and eccentricity, would still intersect each other in the same points, or have common nodes, in which the several fragments would necessarily be found at each revolution. Dr Olbers therefore proposed to examine carefully every month the two opposite parts of the heavens in which the orbits of Ceres and Pallas intersect each other, with a view to the discovery of other planets, which might be sought for in those parts with greater chance of success than in a wider zone embracing the whole limits of their orbits. Subsequent discoveries scarcely support his conjecture, though it has still a great degree of probability.

Theoretical Astronomy.

According to Herschel, the diameter of Pallas is only about 80 English miles, or about one half of that which he assigned to Ceres, while Schroeter estimates it at 2099 miles. Schroeter also found the atmosphere of Pallas to be about two thirds of the height of that of Ceres, or about 450 miles. The light of the planet undergoes considerable variations, the cause of which is uncertain.

Discovery of Juno.

While M. Harding, of the observatory of Lilienthal, near Bremen, was engaged in forming complete charts of the small telescopic stars near the orbits of Ceres and Pallas, with which these planets were likely to be confounded, he determined, on the 2d of September 1804, the position of a small star, by comparing it with the two stars marked 93 and 98 of Pisces in Bode's catalogue. These two stars are situated very near the equator, and at a small distance from one of the nodes of Ceres and Pallas, and exactly in that sort of *defilé* where, according to Dr Olbers, an observer would be certain of detecting in their passage the other fragments of the original planet of which Ceres and Pallas are parts. On the 4th the star was no longer in the same position, but had moved a little to the south-west. On the 5th and 6th M. Harding, by means of a circular micrometer, determined the rate of its motion to be 12′ 42″ in declination to the south, and 7′ 30″ in right ascension, retrograde, the interval between the observations being 24 hours 14 min. 12 sec. From this it was evident that the body belonged to the planetary system. It had then the appearance of a star between the eighth and ninth magnitudes. It was without any nebulosity, and of a whitish colour. A few days

afterwards the elements of its orbit were computed by Gauss. This planet has received the name of Juno, and for its symbol ♆, the starry sceptre of the queen of Olympus.

Juno is distinguished from the other planets by the great eccentricity of her orbit, which is so considerable, that she describes that half of it which is bisected by the perihelion in about half the time which she employs to describe the other half. This planet is somewhat smaller than Ceres and Pallas, and, though free from nebulosity, must have, according to Schroeter's observations, an atmosphere of greater density than that of any of the old planets.

Discovery of Vesta.

The success of M. Harding encouraged Dr Olbers to renew the plan of research which he had pointed out on the discovery of Pallas; and on the 29th of March 1807 he perceived, in the constellation of Virgo, a star of the fifth or sixth magnitude, which he suspected from the first observation to be a new planet. A few subsequent observations rendered this conjecture certain. Dr Olbers left to Gauss the care of giving a name to the new planet, and of determining the elements of its orbit. Gauss named it Vesta, and chose for its symbol ⚶, an altar surmounted with a censer holding the sacred fire. Vesta is the smallest of all the celestial bodies known to us. Her volume is only about a fifteen thousandth part of that of the earth, and her surface is about equal to that of the kingdom of Spain. She is distinguished by the vivacity of her light, and the luminous atmosphere with which she is surrounded.

Jupiter.

Jupiter is by far the largest planet in the system. His diameter is about 11 times, and his volume 1281 times, greater than that of the earth. His distance from the sun is $5\frac{1}{5}$ times the radius of the ecliptic, or nearly 125,000 terrestrial semidiameters, and consequently above 490 millions of miles. His apparent diameter, which, at his mean distance, is 36″·7, and varies between 45″·8 and 30″, would subtend an angle of 3′ 17″ if seen at the same distance as the sun. From Jupiter the sun will appear under an angle of 6′ at most; the sun's disk will appear to be 27 times smaller than when seen from the earth, consequently the light and heat which Jupiter receives from the sun will be only the 27th part of what is received by our globe. His density is ·99239, that of the sun being considered as unity, or is about one fourth of the density of the earth; and a body which weighs one pound at the equator of the earth, would weigh 2·444 pounds if removed to the equator of Jupiter.

Belts of Jupiter.

Plate LXXXV.

Jupiter has the same general appearance with Mars, only the belts on his surface are much larger and more permanent. Their usual appearance, as described by Dr Long, is represented fig. 97–100; but they are not to be seen but by an excellent telescope. They are said to have been first discovered by Fontana and two other Italians, but Cassini was the first who gave a good account of them. Their number is very variable, as sometimes only one, but seldom more than three, may be perceived. Messier at one time saw so great a number that the whole disk seemed to be covered by them. They are generally parallel to one another, but not always so; and their breadth is likewise variable, one belt having been observed to grow narrow, while another in its neighbourhood has increased in breadth, as if the one had flowed into the other: and in this case a part of an oblique belt lay between them, as if to form a communication for this purpose. The time of their continuance is very uncertain: sometimes they remain unchanged for three months, at other times new belts have been formed in an hour or two. In some of these belts large black spots have appeared, which moved swiftly over the disk from east to west, and returned in a short time to the same place; whence the rotation of this planet about its axis has been determined. On the 9th of May 1664, Dr Hooke, with a twelve feet telescope, observed a small spot in the broadest of the three obscure belts of Jupiter; and observing it from time to time, found that in two hours it had moved from east to west about half the visible diameter of the planet. In 1665 Cassini observed a spot near the largest belt of Jupiter, which is most frequently seen. It appeared round, and moved with the greatest velocity when in the middle, but appeared narrower, and moved slower, the nearer it was to the circumference; showing that the spot adhered to the body of Jupiter, and was carried round upon it. This principal, or ancient spot as it is called, is the largest and the most permanent of any hitherto known; it appeared and vanished no fewer than eight times between the years 1665 and 1708: from the year last mentioned it was invisible till 1713. The longest time of its continuing to be visible was three years, and the longest time of its disappearing was from 1708 to 1713. It seems to have some connection with the principal southern belt; for the spot has never been seen when that disappeared, though the belt itself has often been visible without the spot. Besides this ancient spot, Cassini, in the year 1699, saw one of less stability, that did not continue of the same shape or dimensions, but broke into several small ones, whereof the revolution was but 9 hours 51 min.; and two other spots that revolved in 9 hours $52\frac{1}{2}$ min. The changes in the appearance of the spots, and the difference in the time of their rotation, make it probable that they do not adhere to Jupiter, but are clouds transported by the winds, with different velocities, in an atmosphere subject to violent agitations.

By means of the spots, which can be easily observed, the rotation of Jupiter has been determined with considerable precision. The time of rotation, according to Cassini, Maraldi, and others, is 9 hours and between 55 and 56 minutes: Schroeter makes it 9 hours 55 min. 33 sec. The inclination of his equator to his orbit is only 3° 5′ 30″, so that the variations of his seasons must be almost insensible.

The radius of Jupiter being nearly 11 times (10·86) that of our earth, and his rotation being 2·4 times more rapid, it follows that the space passed over by a point on his equator is 26 times greater than that passed over by a point of the terrestrial equator in the same time. Hence the centrifugal force is 26 times greater; and if the spheroidal form of the earth is occasioned by the diurnal motion, we may expect to find the same effects on a much larger scale exhibited in the form of Jupiter. And this is in fact observed to be the case; for according to Struve the compression of Jupiter is about $\frac{1}{14}$th of his radius, the diameter of his equator being to that of his poles as 14 to 13 nearly, while that of the earth is only $\frac{1}{300}$th. The equatorial diameter at the mean distance subtends an angle of 38″·327, the polar 35″·538; and the ellipticity is $0{\cdot}0728 = \frac{1}{13{\cdot}71}$.

The annual parallax of Jupiter is less than 12°, consequently the earth, as seen from Jupiter, will never appear at a greater distance than 11° or 12° from the sun. The digressions of Mars would be 17° 2′, those of Venus 8°, and those of Mercury only 4° 16′. An inhabitant of Jupiter must therefore be probably ignorant of the existence of Mercury, which will be almost constantly plunged in

Theoretical Astronomy.

	Miles.
Inner diameter of smaller ring	146345
Outside diameter of ditto	184393
Inner diameter of larger ring	190248
Outside diameter of ditto	204883
Breadth of the inner ring	20000
Breadth of the outer ring	7200
Breadth of the vacant space, or dark zone	2839

The following measures were taken by Professor Struve, at Dorpat in Russia, in 1828, with a repeating wire-micrometer attached to the large refracting telescope of Fraunhofer, belonging to the observatory at that place, and may be regarded as decidedly the most accurate of any that we possess. (See *Memoirs of the Astronomical Society*, vol. iii. p. 301.)

Outer diameter of the outer ring	40″·095
Inner diameter of the outer ring	35 ·289
Outer diameter of the inner ring	34 ·475
Inner diameter of the inner ring	26 ·668
Breadth of the outer ring	2 ·403
Breadth of the division between the rings	0 ·408
Breadth of the inner ring	3 ·903
Distance of the ring from the ball	4 ·339
Equatorial diameter of Saturn	17 ·991

These dimensions are adapted to the mean distance of Saturn, 9·53877. According to the same excellent astronomer, the inclination of the plane of the ring to the ecliptic is 28° 5′·9.

In observing the ring with very powerful telescopes, some astronomers have remarked, not one only, but several dark concentric lines on its surface, which divide it into as many distinct circumferences. In common telescopes these are not perceptible; for the irradiation, by enlarging the space occupied by each ring, causes the intervals between them to disappear, and the whole seems blended together in one belt of uniform appearance. (See fig. 103.) Struve, however, noticed no trace of the division of the ring into many parts.

Rotation of the ring.

By means of some spots observed on the surface of the ring, Herschel found that it revolves in its own plane in 10 hours 32 minutes 15·4 seconds; and Laplace arrived at the same result from theory. It is particularly worthy of remark, that this is the period in which a satellite, having for its orbit the mean circumference of the ring, would complete its revolution according to the third law of Kepler. This circumstance furnishes a physical explanation of the reason why the ring is able to maintain itself about the planet without touching it; or at least brings the fact within the general law by which the planets are sustained in their orbits. The centrifugal force resulting from its rotation, and the attraction of the planet, suffice to maintain its equilibrium.

Rotation of Saturn.

From observations of some obscure belts, and a very conspicuous spot on the surface of Saturn, Herschel concluded that his rotation is performed in 10 hours 16 minutes, on an axis perpendicular to the belts and to the plane of the ring; so that the planes of the planet's equator and ring coincide. According to the same astronomer, the ratio of the equatorial and polar diameters of Saturn is 2281 to 2061, or nearly 11 to 10. He also believed that the globe of Saturn appeared to be flattened at the equator as well as at the poles. The compression he thought to extend to a great distance over the surface of the planet, and the greatest diameter to be that of the parallel of 43° of latitude, where, consequently, the curvature of the meridians is also the greatest. The disk of Saturn, therefore, resembled a square of which the four corners have been rounded off. According to the more recent measures of Bessel and Main, this idea is proved to be erroneous, and the shape of the planet is that of an exact spheroid of revolution. (See Supplement to Part II.)

Theoretical Astronomy

Saturn is attended by eight satellites, but so small that they can only be seen by the help of powerful telescopes. Huygens first discovered one of these satellites in 1655, the sixth in the order of distance, and the largest. Four others were discovered about twenty years afterwards by Dominic Cassini; and Sir W. Herschel, in 1789, discovered two new satellites, at a time when the ring was visible only in a telescope of forty feet. The orbits of these are interior to those of the five satellites formerly discovered, but exterior to the ring, though so near to it that it is only when the ring disappears that they can be seen. Lastly, an eighth satellite was discovered almost simultaneously by two observers in 1848. All the satellites appear to revolve in the plane of the ring, with the exception of the two nearest.

Satellites of Saturn.

Uranus.

Uranus is the remotest planet belonging to the system, and is scarcely visible excepting through the telescope. His distance from the sun is nineteen times the mean radius of the orbit of the earth, or about 1800 millions of miles; and his sidereal revolution is performed in rather more than 84 years. His diameter is about 35,112 English miles, or nearly six and a half times that of the earth, and, seen from the earth, subtends an angle of only 4″, even at the time of his opposition. The apparent diameter of the sun, seen from this planet, is 1′ 40″; consequently the surface of the sun will there appear 400 times less than it does to us, and the light and heat which is received will be less in the same proportion. Analogy leads us to infer that Uranus is opaque and revolves on his axis, but of this there is no direct proof. Laplace has concluded from theory, that the time of his diurnal rotation cannot be much less than that of Jupiter and Saturn, and that the inclination of his equator to the ecliptic is very inconsiderable. His density is supposed to exceed somewhat that of the earth. Schroeter thinks that certain variations in the appearances of his disk indicate that great changes are going on in his atmosphere.

This planet was discovered by Sir W. Herschel at Bath on the 13th of March 1781. His attention was attracted to it by the largeness of its disk in the telescope, which exceeded that of stars of the first magnitude, while to the naked eye it was scarcely, if at all, visible. In the course of a few days its proper motion became sensible, consequently it could not be a fixed star. Herschel at first took it for a comet, but it was soon perceived that it described a path which, instead of resembling the eccentric orbits of the comets, was almost circular, like that of the planets. It was then recognized to be one of the principal planets of the solar system; and the observations of the last fifty years have not only confirmed this fact, but afforded data from which the elements of its orbit have been determined with great precision. Herschel gave it the name of the *Georgium Sidus*, in honour of his royal patron George III. Foreigners for some time generally called it the *Herschel*, after its discoverer; but the mythological name of *Uranus*, suggested by the late Professor Bode of Berlin, is now generally adopted. In 1787 Herschel discovered that it was attended by two satellites; he subsequently discovered four others, but they have been never reobserved, and the exact number of the satellites of Uranus is still uncertain. Two additional satellites interior to all the others have been recently discovered. (See Supplement to Part II.)

Before concluding this section, it will be proper to take notice of the following curious relation of the numbers

which express, approximately at least, the distances of the planets from the sun. It was first pointed out by Bode, and, though purely empirical, and not even very accurate, served to confirm the German astronomers in their anticipations of the discovery of a new planet between the orbits of Mars and Jupiter.

Let the number 10 be assumed to represent the semidiameter of the earth's orbit; then the semidiameters of the orbits of the other planets may be expressed in round numbers as follows:—

Mercury...4	
Venus.....7	$= 4 + 3\cdot2^0$
Earth.....10	$= 4 + 3\cdot2^1$
Mars.....16	$= 4 + 3\cdot2^2$
Ceres.....28	$= 4 + 3\cdot2^3$
Jupiter...52	$= 4 + 3\cdot2^4$
Saturn...100	$= 4 + 3\cdot2^5$
Uranus..196	$= 4 + 3\cdot2^6$

It will be remarked that every succeeding term of this series of numbers, after the second, is the double of the preceding, minus 4; the general term being $4 + 3\cdot2^{n-2}$, commencing with Venus, and n indicating the rank of the planet.

A view of the proportional magnitudes of the orbits and disks of the planets, as also of the comparative magnitudes of the sun seen from each planet, is given in fig. 104.

Sect. IV.—*Of the Orbits of the Satellites.*

In order to establish a theory of the motions of the satellites, the first thing necessary is to ascertain the directions in which they move with reference to the primary planet. Now, it is observed that their motion is sometimes towards the east, and at other times towards the west; but that the satellites are never occulted except in passing from the west to the east of the planet. When an occultation occurs the satellite is always moving eastward; on the other hand, the satellite is always moving westward when it appears on the planet's disk. From this it results that the true motions of the satellites around the planets are from west to east, according to the order of the signs, or in the same directions as the motions of the planets about the sun. This fact, which holds true of the moon, and the satellites of Jupiter and Saturn, is one of the most remarkable in the planetary system. With regard to the satellites of Uranus, their motions are performed in orbits almost perpendicular to the ecliptic; they cannot therefore with propriety be said to be either direct or retrograde.

The eclipses of the satellites of Jupiter present an easy method of determining their mean motions and periodic times; and, by reason of the small inclinations of the orbits, these are of very frequent occurrence; for the first three satellites traverse the shadow of Jupiter in every revolution, and the fourth only passes by it sometimes, in consequence of the greater inclination of its orbit. If the instants can be observed at which a satellite enters and emerges from the shadow, the middle point of time between these two instants will be that of the heliocentric conjunction of the satellite with its primary. The interval between two central eclipses gives the *synodic period* of the satellite; whence, since the motion of the primary is known, the *sidereal period* of the satellite, and its mean angular motion with regard to the straight line joining the centres of the sun and the planet, are easily deduced. Instead of two successive eclipses, it is preferable to compare two that are separated from each other by a long interval of time; the interval divided by the number of sidereal revolutions will give the mean time, unaffected by any periodic inequalities which may exist in consequence of the mutual action of the satellites on one another. In order to render the result as accurate as possible, those eclipses are chosen which take place when the planet is nearly in opposition.

The distances of the satellites from their primary are ascertained by measurement with the micrometer, at the time of the greatest elongations. On comparing the distances with the times of revolution, the beautiful law of Kepler is found to prevail; and, as in the system of the planets, so in the various systems of the satellites, the squares of the periodic times vary as the cubes of the mean distances from the central body. The distances of the satellites of Jupiter and Saturn, compared with the diameters of their respective primaries, are represented in fig. 105.

The inclinations of the orbits of the satellites of Jupiter, and the positions of their nodes, together with the other elements of their elliptic motion, are determined by means of their eclipses. The plane of the orbit of the first satellite nearly coincides with the plane of the equator of Jupiter, the inclination of which to the plane of his orbit is 3° 5′ 30″. The inclination of the orbit of the second to the plane of the planet's equator is 27′ 49″·2. Its nodes have a retrograde motion on that plane, and go through an entire circuit in the space of 30 years. The orbit of the third is inclined to the equator of Jupiter in an angle of 12′ 20″; and the line of the nodes retrogrades through a whole circumference in 142 tropical years. Hence the inclinations of the orbits of these two satellites to the orbit of Jupiter are variable; that of the second varying between 3° 19′ 24″·6 and 2° 51′ 35″·4, and that of the third between 3° 17′ 50″ and 2° 53′ 10″. The inclination of the orbit of the fourth satellite to the orbit of Jupiter is also variable. Its nodes have a retrograde motion, and complete a revolution in 531 years. Since the middle of the last century the inclination of this satellite has been observed to increase, and the motion of its nodes to diminish. (Laplace, *Mécanique Céleste*, tome iv. livre viii.)

The orbits of the four satellites are doubtless elliptical, but those of the first and second are so small that it has been found impossible to determine their eccentricity. The eccentricity of the third is perceptible, that of the fourth much more so. According to Laplace, the greatest equation of the centre of the third, at its maximum in 1682, amounted to 13′ 16″·4, and at its minimum in 1777, only to 5′ 7″·5. The eccentricity of the orbit of the fourth is still greater, and also subject to considerable variations. The line of the apsides has a direct motion, amounting to 42′ 58″·7 annually. The great in-

Theoretical Astronomy.

fluence of the compressed figure of Jupiter on these elements gives each of the orbits an eccentricity peculiar to it; but each is also affected by the eccentricities of the others. The mutual perturbations of the satellites greatly affect their motions, and render their analytical theory exceedingly complicated and difficult.

On comparing the mean longitudes with the mean motions of the first three satellites of Jupiter, Laplace discovered the two following relations, which, by reason of their remarkable simplicity, may perhaps be regarded as among the most curious discoveries ever made in astronomy. Denoting by m', m'', m''', the mean motions of the three satellites respectively, and their mean longitudes by l', l'', l''', these laws are expressed by the formulæ,

$$m' + 2m''' - 3m'' = 0$$
$$l' + 2l''' - 3l'' = 180°;$$

that is to say, the mean sidereal motion of the first, added to twice that of the third, is equal to three times that of the second; and the mean longitude of the first satellite, plus twice that of the third, minus three times that of the second, is always equal to a semicircumference. The first of these relations is true of the synodical as well as of the sidereal revolutions; and it follows from the second, that the first three satellites can never be eclipsed at the same time, because in that case their longitudes would be equal, or $l' + 2l''' - 3l'' = 0$. These results of theory agree so nearly with observation, that we are tempted to regard them as rigorously exact, and to ascribe the slight differences that may be perceptible to the unavoidable errors of observation, and to the periodic inequalities in the motions of the satellites, by reason of which their true motions are alternately greater and smaller than their mean motions. We must therefore infer that these relations depend on a physical cause, by which they will be preserved for ever, or at least during a long series of ages, notwithstanding the small oscillations to which, from various sources of perturbation, the mean longitudes of the satellites are subject.

From observations of the eclipses of Jupiter's satellites, Roemer was led to the very important discovery of the successive propagation of light. The times at which these eclipses happen are found to differ from the times computed from the sidereal revolutions of the satellites, being sometimes earlier and sometimes later, according to the position of Jupiter relatively to the sun and the earth. When Jupiter is in opposition with the sun, and his distance from the earth consequently less than his distance from the sun by the whole radius of the earth's orbit, the satellites are eclipsed sooner than they ought to be according to computation. On the contrary, when Jupiter is in conjunction, and his distance from the earth greater than his distance from the sun by the same quantity, the eclipses happen later. These differences, which are exactly the same for all the satellites, cannot be ascribed either to the eccentricity of the orbit of Jupiter, or to inequalities in their motion; for the oppositions and conjunctions of the planet correspond successively to all the different points of his orbit, and the eclipses also happen when the satellite is at different points of its own orbit. The simplest and most natural way of explaining the phenomenon is to suppose that the light reflected from the satellites is not transmitted to the earth instantaneously, but occupies a sensible portion of time in traversing the diameter of the terrestrial orbit. When Jupiter is near his conjunction, the eclipses are observed to happen about 16 minutes 26 seconds later than when he is near his opposition; the difference between his distances from the earth in these two positions is equal to the diameter of the earth's orbit, supposing the orbits to be circular: it follows, therefore, that light employs 16 minutes 26 seconds in traversing the terrestrial orbit, and consequently the half of that time, or 8 minutes 13 seconds, in coming from the sun to the earth. The exact agreement of this hypothesis with observation renders its truth unquestionable. The fact of the successive transmission of light led to another discovery of the utmost importance in astronomy, namely, the aberration.

Theoretical Astronomy

The eclipses of Jupiter's satellites are useful in determining the longitude of places on the earth, and on this account the theory of the motions of these bodies has been cultivated with the most laborious care. The epochs at which the eclipses take place are calculated in advance, and inserted in the *Ephemerides*. On comparing these epochs, computed for a given meridian, with the immediate results of observation made in another place at a given hour, the difference of time is obtained, whence the difference of longitude is immediately deduced. The method is the same as for the eclipses of the moon. Unfortunately, by reason of the magnifying power required to render the satellites visible, it cannot be employed at sea, the instability of the vessel rendering the telescopes unserviceable. The tables of Delambre, which were computed from the theory of Laplace, and the comparison of an immense number of observations, give the places of the satellites with all the precision which it is perhaps possible to obtain.

The satellites of Saturn have not the practical utility of those of Jupiter, because, by reason of their great distance, their eclipses are invisible; and indeed some of them cannot be perceived at all, excepting through telescopes of extraordinary power. Their periods, mean motions, and some of the other elements of their orbits, are determined by the micrometrical measurement of their greatest digressions from their primary. At the time of their greatest digressions they are always situated in the same straight line with the greater axis of the ring, and their distances from Saturn are then equal to the semi-transverse axes of their apparent orbits. In their conjunctions the minor axes of their apparent ellipses seem only half as great as their transverse axes, whence it is inferred that the sine of their inclination is one half, and consequently that the inclination itself is about 30°, which is nearly the inclination of the ring. Hence the satellites seem to move in the plane of the ring. The only one which deviates considerably from that plane is the seventh. From certain observations made by Bernard in 1787, Lalande makes the inclination of this satellite 22° 42′ to the orbit of Saturn, or 24° 45′ to the ecliptic. There exists, however, considerable uncertainty with regard to the inclination of the orbits of the satellites, as well as with regard to that of the ring.

According to the theory of Laplace, the spheroidal figure of Saturn, of which the compression is very considerable, must maintain the ring, and the orbits of the interior satellites, in the plane of his equator. All that is certain is, that the inclination of the orbits of the first five satellites to the equator of the planet is insensible at the distance of the earth; consequently all the satellites, excepting the seventh, and probably also the sixth, will appear, as well as the ring, to move in the plane of the equator. The orbit of the seventh satellite preserves the same mean inclination to the plane of the equator of the planet; and the line of its nodes has a retrograde motion nearly uniform.

The orbit of the sixth satellite is elliptical. For the meridian of Paris its longitude in 1800 was 67° 25′ 47″; that of its inferior apside 203° 35′ 7″. Its mean motion in 36525 days is 2290 revolutions + 202° 12′; in one day

Theoretical Astronomy.

22° 34′ 37″·186. The eccentricity is ·04887; and its greatest equation 5° 36′ 8″. By particular observations on this satellite, Bessel found its inclination to the ecliptic to be 24° 30′, or 25° 55′; differing very sensibly from that of the ring or the equator of the planet. It is, however, not improbable that these two planes may have some inclination to each other. (Delambre, *Astronomie Théorique et Pratique*, tome iii. p. 510.)

The satellites of Uranus can be perceived with still greater difficulty than those of Saturn. The orbits of these satellites are almost perpendicular to the ecliptic. The elements of the second and fourth have been determined by actual measurement; the periods of the two others have been theoretically deduced from the third law of Kepler. The inclination of the fourth is 89° 30′, or 90° 30′, and the ascending node 171° or 249°, according as it is conceived to be direct or retrograde.

The following table exhibits the mean distances and sidereal revolutions of the satellites of Jupiter, Saturn, and Uranus (all, except the 2d and 4th, very doubtful).

CHAP. V.

OF COMETS.

The comets form a class of bodies belonging to the solar system, distinguished from the planets by their physical appearances and the great eccentricities of their orbits. By reason of the smallness of their diameters, and a nebulosity which renders them ill adapted to reflect the rays of light, the greater part of them are only visible in the telescope, and continue to be so only during a short period of time; for as they advance to and recede from the sun almost in straight lines, and with prodigious velocities, they are soon carried far beyond the limits of vision. They have received the name of comets (*coma*, hair) from the *bearded* appearance which they frequently exhibit.

SECT. I.—*Of the Orbits of Comets.*

The comets are not more remarkably contrasted with the planets in the singularity of their physical appearances, than in the directions of the paths which they follow in space. While the orbits of all the planets are confined within a narrow zone, or to planes not greatly inclined to the ecliptic, those of the comets are inclined in all possible angles, and some of them are even observed to be perpendicular to the ecliptic. Nor is the contrast less striking with regard to the figures of the orbits, which, instead of being nearly circular, like those of the planets, have the appearance of being almost rectilinear. Kepler was of opinion that the cometary orbits are straight lines; Cassini supposed them to be very eccentric circles; and Tycho was for some time of the same opinion, but he afterwards found that the hypothesis of the eccentric circle would not satisfy the observations of the comet of 1577. Hevelius seems to have been the first who discovered, by means of a geometrical construction, that the orbits might be represented by parabolas; and Dörfel first calculated their elements on this hypothesis. After it was known, however, that certain comets return to the sun in the same orbits, it became necessary to adopt an opinion, already probable from analogy, that, in conformity with the laws of Kepler, the cometary orbits are ellipses having the sun in one of the foci. This hypothesis is now universally admitted; but as the ellipses are in general extremely elongated, and the comets are only visible while they describe a small portion of their orbits on either side of their perihelia, their paths during the time of their appearance differ very little from parabolas; whence it is usual, on account of the facility of computation, to assume that they really move in parabolic curves. Newton employed the hypothesis of an elliptic motion to compute the orbit of the famous comet of 1680. Since that time the orbits of more than a hundred and fifty different comets have been computed on the elliptic hypothesis, and their elements determined so as to satisfy all the observations. It is possible that the orbits of some comets may be in reality parabolic; but in this case the comet, after having passed its perihelion, would recede to an infinite distance from the sun, and never again visit our system. Burckhardt imagined that the observations of the comet of 1771 were best represented by supposing the orbit to be an hyperbola. In fact, it is demonstrated in the *Principia*, and every treatise on Physical Astronomy, that the species of curve which one body describes about another, in virtue of an attractive force varying inversely as the square of the distance, depends only on its velocity of projection. The curve must necessarily be a conic section; but it may be an ellipse, a parabola, or an hyperbola, according as the primitive impulsive force falls within or exceeds certain assignable limits.

Theoretical Astronomy.

If the comets moved in parabolas or hyperbolas, and had consequently only a temporary connection with the solar system, the determination of their orbits would be a matter of mere curiosity, and of no consequence whatever to astronomy. But it is only by the accurate determination of the elements of their orbits that it can be discovered whether those bodies ever revisit the system; for the appearances which they exhibit, depending on the situation of the earth in its orbit with relation to them at the time they are visible, are far too variable and uncertain to afford any sure means of recognising them. The comet of 1811 was scarcely visible in the months of April and May; it was subsequently lost in the sun's rays, and, having passed its perihelion, re-appeared in August with a splendour and magnificence that rendered it an object of admiration. It is therefore only by observing that a comet follows the same orbit in its successive returns to the sun that we can be assured of its identity. But even the determination of the orbit is not always sufficient to lead to the detection of a comet in a

subsequent revolution; for if, in the course of the previous one, it came within the sphere of attraction of Jupiter, or any of the larger planets, the elements of its orbit may have been greatly or entirely changed. The orbit of the comet of 1770 was calculated by Lexell, and subsequently by Burckhardt, and both these astronomers found that the observations could only be represented by an ellipse in which the time of revolution was five years and a half; yet the comet has never been seen since, or at least seen moving in the same orbit. Hence it is concluded with certainty that the attraction of Jupiter, near which planet it approached, was so great as to compel it to move in a totally different ellipse. Other causes also conspire to render the chances of the discovery of periodic comets extremely small. In the first place, it is only within a very small portion of their orbits that they are visible; and this, on account of its proximity to the sun, is passed over with inconceivable rapidity. But in proportion as they recede from their perihelia the solar action diminishes; and, towards the aphelion of its orbit, a comet may be almost motionless, and for this reason not return for thousands of years. In the second place, it may happen, that during the greater part of the time the comet continues in the visible portion of its orbit, it may rise above the horizon only during the day, in which case it will be invisible, and may consequently pass through our system without being observed. The comet of 1818 was present in all its splendour long before it became visible, but in full day. Seneca relates a very curious instance of one having been seen during a total eclipse of the sun, in the year 60 before our era. A third cause of uncertainty consists in the difficulty of observing their true places with sufficient precision to enable the elements of their orbits to be exactly determined. The small comets are only nebulous points, which can be distinguished with difficulty; the larger ones are surrounded with a variable, ill-defined, and indistinct nebulosity. The comet of 1729 continued visible during six months: its orbit was computed by three different astronomers, whose results were far from coinciding. The same uncertainty exists with regard to the orbits of several other comets. When, therefore, all these circumstances are taken into consideration, it will not appear surprising that, although the elements of above 150 comets have been computed, there are only three which are certainly known to have been observed in their successive revolutions.

The most remarkable periodic comet with which we are acquainted was made known to astronomers by Dr Halley. That active and indefatigable genius, having perceived that in 1682 the elements of its orbit were nearly the same as those of two comets which had respectively appeared in 1531 and 1607, concluded that the three orbits belonged to the same identical comet, of which the periodic time was about 76 years. After a vague estimate of the perturbations it must sustain from the attraction of the planets, Dr Halley predicted its return for 1757,—a bold prediction at that time, but justified by the event, for the comet again made its appearance as was expected, though it did not pass through its perihelion till the month of March 1759, the attraction of Jupiter and Saturn having caused, as was computed by Clairaut previously to its return, a retardation of 618 days. This comet had been observed in 1066; and the accounts which have been preserved represent it as having then appeared to be four times the size of Venus, and to have shone with a light equal to a fourth of that of the moon. History is silent respecting it from that time till the year 1456, when it passed very near to the earth: its tail then extended over 60° of the heavens, and had the form of a sabre. An object so striking and so terrific could not fail, in a superstitious age, to excite universal dismay, and be regarded as portentous of the greatest calamities to the human race, if not of the destruction of the world. Accordingly Pope Calixtus ordered public prayers to be said over Christendom, in which he exorcised the comet, and the Turks, who had at that time made themselves masters of Constantinople, and overthrown the eastern empire. Dr Halley's comet returned to its perihelion in 1835; and the splendour of its appearance rendered it once more an object of universal interest; it was well observed in almost every observatory. The following table of its elements in 1835 is given by Pontécoulant (*Théorie Analytique du Système du Monde*, tome ii. p. 147):

Instant of the passage through the perihelion in October 1835	31d.2
Semiaxis major	17 ·98355
Ratio of the eccentricity to the semiaxis major	0 ·967453
Place of the perihelion on the orbit	304° 34′ 19″
Longitude of the ascending node	55 6 59
Inclination	17 46 50

Two other famous comets whose periodic returns have been verified by observation have received the names of Encke and Biela, the astronomers who first computed their orbits, or recognised them as having been observed in their previous revolutions. The first returns to its perihelion in 1208 days, and the second in 2440 days. Encke's comet, although its identity was not discovered till 1818, has been frequently observed, as in 1789, 1795, 1801, and 1805, and on these occasions it exhibited very different appearances, having been seen with and without a nucleus, with and without a tail,—circumstances which account for its having so long escaped being recognised as a regular attendant on the sun. In its returns to its perihelion in 1808, 1812, and 1815, it escaped detection; but it re-appeared in 1818, and it was from the observations of this year that Encke computed the elliptic elements of its orbit. On its next return, in 1822, it was invisible in Europe; but it was observed at Paramatta, in New South Wales, during the whole month of June, and the time of its perihelion passage was found to differ only by about three hours from that previously computed by Encke. On its returns in 1825 and 1828 its observed and computed places agreed equally well. The following, according to Pontécoulant, are its elements for 1829–30, computed from the observations at Paramatta:

Passage through the perihelion, 1829, January 10d.573	
Mean diurnal motion	1069 ·5570
Eccentricity	0 ·8446862
Place of perihelion	157° 18′ 35″
Longitude of ascending node	334 24 15
Inclination	13 22 34.

Encke's comet presents in some respects a considerable analogy with the planet Ceres, the inclination and greater axis of its orbit being the same, while its sidereal revolution is only 46 days shorter than that of Vesta. The orbit is, however, greatly more elongated, for its perihelion falls within the orbit of Mercury, and its aphelion is situated between Jupiter and the new planets. The perturbations it sustains are chiefly occasioned by the attraction of Jupiter, that of the earth and Venus being extremely small, while the action of Mercury is insensible.

A third comet of short period with which our knowledge of the solar system has been enriched receives its name from Biela, by whom it was first perceived in Bohemia, on the 27th of February 1826. The parabolic elements computed from the first observations presented a striking resemblance with those of two comets which had been observed in 1772

and 1806, which induced MM. Clausen and Gambart, the first at Marseilles and the second at Altona, to compute the elements of the three comets on the hypothesis of elliptic orbits; and, after some attempts, each found an ellipse which represented all the observations so accurately as to leave no doubt of the identity of the comet. Its period is six years and about nine months, and it returned to its perihelion in November 1832, about the same time with Encke's. The following table of its elements was computed from the observations of 1826, and the theory of the perturbations (Pontécoulant, tome ii. p. 158):—

Passage through the perihelion 1832, November	27d.4808
Eccentricity	0·7517481
Place of the perihelion	109° 56′ 45″
Longitude of ascending node	248 12 24
Inclination	13 13 13
Semiaxis major	3·53683

Besides the periodical comets which have been mentioned, there are two others of long period, of which the orbits are supposed to be known, though their returns to their perihelia have not yet been verified. The first is that which appeared in 1680, and of which Newton computed the period to be 575 years. It may therefore be identical with those which are recorded in history to have appeared in 1106, 531, 34 B. C. and 619 B. C. The second is that which appeared in 1556, and is supposed to have made a former visit in 1264. This comet is expected to appear again in 1858.

The following table, taken from one given by Delambre in the third volume of his *Astronomie*, shows the comparatively small distances within which the greater part of the comets hitherto observed approach to the sun, and the apparently fortuitous inclinations of the planes of their orbits to that of the ecliptic. Supposing the sun's distance from the earth to be unity, then, of 120 comets, there are

5 whose perihelion distance is less than	0·1
3	between 0·1 and 0·2
6	0·2 and 0·3
11	0·3 and 0·4
10	0·4 and 0·5
22	0·5 and 0·6
12	0·6 and 0·7
11	0·7 and 0·8
8	0·8 and 0·9
9	0·9 and 1
21	1 and 2
1	equal to 2·293
1	4·069.

Of the same number there are

4 whose inclination is between	1° and 5°
3	5 and 10
4	10 and 15
3	15 and 20
2	20 and 25
2	25 and 30
7	30 and 35
2	35 and 40
4	40 and 45
1	45 and 50
3	50 and 55
4	55 and 60
7	60 and 65
3	65 and 70
3	70 and 75
3	75 and 80
4	80 and 85
2	85 and 90.

The motions of the above 61 are direct; those of the remaining 59 are retrograde, and their orbits are distributed over the whole quadrant in the same random manner. This circumstance sufficiently indicates that the mechanical causes, whatever they were, which gave the same direction to the two motions of translation and rotation of all the planets and satellites, exercised no influence on the comets. Hence many astronomers have entertained the idea that these bodies have only a casual or transient connection with the planetary system.

Sect. II.—*Of the Appearances and Physical Constitution of Comets.*

Of all the celestial phenomena, those of the comets are the most striking, and the most calculated to impress the ignorant with the idea of supernatural agency. Appearing suddenly in the heavens, and under aspects the most uncommon and terrific, they have been almost universally regarded as visible demonstrations of the wrath, and harbingers of the vengeance, of offended deities. These superstitious terrors, arising from that vain propensity of the mind of man to regard the universe as created for himself alone, have only been dissipated by the progress of sound philosophy, and a more extended acquaintance with the riches of nature, and the endless variety of her productions.

The appearances exhibited by the comets are exceedingly diversified, and sometimes extremely remarkable. That which appeared in the year 134 B. C., at the birth of Mithridates, is said to have had a disk equal in magnitude to that of the sun. Ten years before this, one was seen, which, according to Justin, occupied a fourth part of the sky, that is, extended over 45°, and surpassed the sun in splendour. Another, equally remarkable, appeared in the year 117 of our era; and in 479 there was one of which the disk, according to Freret, was of such magnitude that it might have occasioned the extraordinary eclipse of the sun which took place about that time. In 400 one was observed, which is said, on the authority of Gainas, to have resembled a sword, and to have extended from the zenith to the horizon. That of 531 was of greater magnitude still, and its appearance more terrific. Those which appeared in 1066 and 1505 exhibited disks larger than that of the moon. It is, however, highly probable that all these accounts have been greatly exaggerated, through the ignorance and credulity of the historians by whom they are related; for, since comets have been observed by astronomers, no instances have occurred in which their magnitudes and appearances have been so extraordinary. The most remarkable among those of which we possess accurate accounts appeared in the years 1456, 1618, 1680, 1744, 1759, 1769, 1807, and 1811.

Fig. 106 is a representation of the celebrated comet of 1680, taken from Lemonnier's *Histoire Céleste*. It exhibits the nucleus or disk with its surrounding atmosphere. Above is a sort of ring, wider at the summit, and narrower towards the sides. A *coma* or beard succeeds the ring; and lastly, an immense train of luminous matter, somewhat less vivid than the nucleus. This luminous train, or tail as it is called, is by far the most singular and striking feature presented by the comets. That of the comet of 1744 was one of the most remarkable. It was divided into six branches, all diverging, but curved in the same direction; and between the branches the stars were visible. It is represented in fig. 107. The tail of the comet of 1811 was composed of two diverging parts inclined to each other in an angle which varied from 90 to 15 or 20 degrees. These branches were curved in opposite directions, and descended from the nucleus like a veil: between the

Plate LXXXVII.

Theoretical Astronomy

branches, and surrounding the nucleus, was a space comparatively obscure.

The nucleus, which is the densest and most luminous part, may be said to form the true body of the comet. It is, however, so far from having the dense and solid appearance of the planets, that some astronomers have imagined it to be diaphanous, and even supposed that they have observed stars through it. But supposing such an observation certain, it may be accounted for with much greater probability by the effects of refraction; and it is besides extremely difficult to distinguish the nucleus from the surrounding nebulosity. If the nucleus were an opaque globular body, it would exhibit phases like Venus or Mars, according to its different positions with relation to the sun and the earth; and such were observed, or at least were supposed to be observed, in the case of the comet of 1682, by Hevelius, Picard, and Lahire. But the nebulosity renders the phases exceedingly obscure and indistinct, and prevents the true body of the comet from being seen; in the same way as a globe of roughened glass prevents us from distinguishing the form of the flame of an inclosed lamp. The real nucleus has probably never been observed by any astronomer; and, from the appearances, we are led to infer that a comet, at least near its perihelion, is only an agglomerated mass of vapours. As it recedes from the perihelion, the vapours may be condensed by cold into a solid substance. This hypothesis is also favoured by the extreme smallness of the density of the comets, which is known certainly from the circumstance that they produce no appreciable effect on the motions of the planets. The comet of 1770 traversed the system of Jupiter's satellites without causing any sensible perturbation of those small bodies. This comet also passed very near the earth; and Laplace calculated, that if its mass had been equal in density to that of the earth, the effect of its attraction would have increased the length of the sidereal year by two hours and twenty-eight minutes. But since its influence was altogether insensible, it is certain that its mass was not equal to the five thousandth part of that of the earth, and probably much inferior even to this quantity.

If the nuclei of comets are solid, the matter of which they are composed must be extremely fixed in order to enable them to resist the intense heat they necessarily experience in their approaches to the sun. According to the computation of Newton, the great comet of 1680, at its perihelion, was only distant from the sun by the 163d part of the semidiameter of the earth's orbit, where it would be exposed to a heat above 2000 times greater than that of red-hot iron,—a temperature of which we can form no conception, and which would instantly dissipate any substance with which we are acquainted.

In order to explain the singular phenomena of the train of light which frequently attends the comets, the following theory was proposed by Newton. The comets move in very eccentric orbits, and consequently, towards their perihelia, approach very near to the sun. The excessive degree of heat they sustain near this point of their orbits must convert into vapour every substance capable of vaporization; and hence the prodigious extent of their atmosphere in comparison of the smallness of their nuclei. When this atmosphere has acquired all the volatility of which it is susceptible, the impulsion its vapours receive from the solar rays, however feeble that force may be conceived to be, is sufficient to put them in motion, and drive them off in a direction opposite to the sun. Thus it is remarked, that the tail becomes most conspicuous after the comet has passed the perihelion, and that its direction, as was first observed by Appian, is the straight line joining the centres of the sun and comet. The slight curvature which is generally observed may be accounted for by combining the motion given to the vapours by the impulsion of the sun's rays with the motion of the comet in its orbit; for the detached vapours are driven by the impact of the luminous particles beyond the sphere of the comet's attraction, and consequently cease to follow the direction of the nucleus. Hence the curvature of the tail must be greatest towards its extremity; and this is observed to be actually the case. It may be remarked, however, that although this hypothesis serves to explain the phenomena when all the branches of the tail are bent in the same direction, it is inapplicable when the directions of the curvature are opposite, as was the case with regard to the comet of 1811. In fact, no ultimate reasons for several of the phenomena exhibited by comets have yet been given which can be considered as entirely satisfactory.

Theoretical Astronomy.

The discovery of the periodic returns of certain comets necessarily put an end to the apprehensions and terrors which their unusual appearances were well calculated to excite, and proved them to be permanent bodies belonging to the same system, and acted on by the same laws, as the planets. But this very discovery gave rise to apprehensions of another kind, more natural, though, when closely examined, hardly more reasonable. Since the comets are so numerous, and their orbits traverse the planetary system in all directions, and come within the orbit of the earth, is there not a probability that some of them may come into contact with our globe, and destroy it by the direct collision; or at least approach so near as to produce the most disastrous effects by their attraction? Halley found that the comet of 1680 had approached its perihelion about the time of the universal deluge, and thought it probable that that great catastrophe might have been immediately occasioned by the earth's being enveloped in the aqueous vapours of its tail,—an idea which was afterwards more fully developed by Whiston. Lalande and Maupertuis have minutely detailed the terrible effects which might be produced by the shock of a comet, or even by its approach to our earth. The vapours brought by the tail would mingle with the atmosphere, and render it less respirable. The attraction of the nucleus would destroy the equilibrium of the ocean, and cause extraordinary inundations, which might sweep off the greater part of the human species. The direct shock might change the position of the earth's axis, or even cause the earth to leave its present orbit. It might then become a satellite of the comet, and be carried away with it to the extreme limits of the sun's attractive influence: or, as the mass of the comet would probably be inferior to that of the earth, the earth would carry the comet along with it in its orbit, and thus acquire a second moon: and it has even been surmised that the moon we actually enjoy may owe its origin to an accidental occurrence of this kind. But all these reveries have disappeared before the calculus, by which it is demonstrated that the orbit of the moon can never at any time have been greatly different from what it now is. The collision of a comet with the earth is not an impossible event; though so infinitely little probable, that it can never excite any just cause of alarm. The conjunctions of the planets anciently caused terrors still more unreasonable; and the eclipses, which now scarcely attract the notice of the vulgar, long rivalled the comets in the terrors which they occasioned to the inhabitants of the earth.

Various opinions have been entertained respecting the nature, and formation, and uses of the comets. Newton supposed that, as some of them pass so near to the sun as

Theoretical Astronomy.

to be involved in all probability within his atmosphere, the resistance they must consequently experience will cause them to approach nearer and nearer to the great luminary at every successive revolution, till at last they are precipitated into his substance; hence their use in the system may possibly be to repair the losses which the sun sustains from the constant emission of light. Whatever destinies they may be appointed to fulfil, the recent discovery of several comets of short periods must be regarded as of great importance to astronomy, inasmuch as the frequency of their appearance will enable observers to take notice of any great changes with which either their masses or orbits may be affected.

With regard to the actual number of comets belonging to the solar system, there are no data from which we can form any probable conjecture. Those only (with two or three exceptions) which come within the orbit of the earth are visible to us, and nearly 200 have been observed since the discovery of the telescope. If, then, we suppose them to be equally distributed throughout the whole system, it would follow that the number of comets coming within the sphere of Uranus, the radius of which is twenty times that of the earth's orbit, amounts to 1,200,000 (the cube of 20 multiplied into 150), assuming the average period of their revolutions to be that in which 150 have come within the sphere of the earth. Such computations, however, are scarcely deserving of notice.

On the subject of comets, the reader may consult Aristotle, *Meteorol.* lib. i. cap. vi.; Seneca, *Quæst. Natural.* vii.; Hevelii *Cometographia;* Newton, *De Mundi Systemate,* and *Princip.* lib. iii. prop. 42; Halley, *Synopsis Astronomiæ Cometicæ,* and *Phil. Trans.* vol. xxiv.; Euler, *Mém. Acad. CHAP. VI.

OF THE FIXED STARS.

After having treated of the different classes of bodies which compose the solar system, it only remains for us to inquire what observation has been able to discover respecting that innumerable host which "studs the galaxy,"—that multitude of brilliant points which, on account of their always sensibly retaining the same relative positions, have received the name of *Fixed Stars.*

SECT. I.—*Of the Arrangement of the Fixed Stars.*

The great multitude of stars visible even to the naked eye renders it impossible to distinguish each by a particular name: astronomers have accordingly, for the sake of reference, formed them into groups, to which they give the name of *Constellations* or *Asterisms.* To the different constellations the early astronomers gave the names of men, and animals, and other familiar objects, from some fancied resemblances or analogies, which, for the most part, are not easily traced. These denominations, consecrated by ancient usage, are preserved in modern catalogues; and the practice of delineating the object itself on celestial globes and charts has been only recently, if it has yet altogether, been abandoned. The ancients likewise distinguished some of the brightest stars in the different constellations by particular names; but when it was wished to include others less conspicuous, it became necessary to have recourse to a different mode of proceeding. According to the usual method, first introduced by Bayer in his *Uranometria,* each of the stars in every constellation is marked by a letter of the Greek alphabet, commencing with the most brilliant, which is designated by α, the next most conspicuous is called β, the third γ, and so on. When the Greek letters are exhausted, recourse is had to the Roman or Italic; but even with the help of these the nomenclature cannot be extended far, and the simplest and most comprehensive method is undoubtedly to employ the ordinal numbers to particularize the stars belonging to each constellation. It requires to be remarked, that the order of the letters indicates only the relative brilliancy of the stars in the same constellation, without any reference to those in other parts of the heavens. Thus α *Aquarii* is a star of the same order of brightness as γ *Virginis.* The stars of the first order of brightness are likewise denominated stars of the *first magnitude;* those of a degree inferior in brightness are said to be of the *second magnitude;* and so on with the third, fourth, &c. Below the sixth the same denominations are continued; but the stars of the seventh and inferior magnitudes are no longer visible to the naked eye, and are therefore called *telescopic stars.* It is obvious that, in conferring these denominations, it has been assumed that the brilliancy of the stars is proportional to their magnitudes,—an hypothesis at least extremely doubtful. The terms are however only used for the sake of distinction, and no exact ideas can be attached to the numbers. Observers are even at variance on the subject, certain stars being regarded by some of them as being of the first, which are considered by others as being only of the second magnitude.

Theoretical Astronomy.

A few stars have preserved the names conferred on them by the Greek or Arabian astronomers. Some of those names, belonging to stars of the first magnitude, are the following:—*Sirius,* in the right shoulder of Orion; *Rigel,* in his left foot; *Aldebaran,* or the eye of the Bull; *Capella; Lyra; Arcturus; Antares; Spica Virginis; Regulus,* or the heart of the Lion; *Canopus; Fomalhaut; Acharnar,* &c.

The number of constellations given by Ptolemy is 48. They do not comprehend all the stars in his catalogue, and those not included in the figures are called by him *unformed stars* (αμορφωτοι, *informes*), and given at the end of that constellation to which they are nearest. The following table includes Ptolemy's constellations, and those which have been added by the moderns.

PTOLEMY'S CONSTELLATIONS.

North of the Zodiac.

1. Ursa Minor,	The Little Bear.
2. Ursa Major,	The Great Bear.
3. Draco,	The Dragon.
4. Cepheus,	Cepheus.
5. Bootes, *Arctophylax.*	
6. Corona Borealis,	The Northern Crown.
7. Hercules, *Engonasin,*	Hercules kneeling.
8. Lyra,	The Harp.
9. Cygnus, *Gallina,*	The Swan.
10. Cassiopeia,	The Lady in her Chair.
11. Perseus,	Perseus.
12. Auriga,	The Waggoner.

Theoretical Astronomy

13.	Serpentarius, *Ophiuchus,*	Serpentarius.
14.	Serpens,	The Serpent.
15.	Sagitta,	The Arrow.
16.	Aquila, *Vultur,* et Antinous,	The Eagle and Antinous.
17.	Delphinus,	The Dolphin.
18.	Equulus, *Equi Sectio,*	The Horse's Head.
19.	Pegasus, *Equus,*	The Flying Horse
20.	Andromeda,	Andromeda.
21.	Triangulum,	The Triangle.

In the Zodiac.

22.	Aries,	The Ram.
23.	Taurus,	The Bull.
24.	Gemini,	The Twins.
25.	Cancer,	The Crab.
26.	Leo,	The Lion, to which he joined some stars of Berenice's Hair.
27.	Virgo,	The Virgin.
28.	Libra, *Chelæ,*	The Scales.
29.	Scorpio,	The Scorpion.
30.	Sagittarius,	The Archer.
31.	Capricornus,	The Goat.
32.	Aquarius,	The Water-bearer
33.	Pisces,	The Fishes.

Southern Constellations.

34.	Cetus,	The Whale.
35.	Orion,	Orion.
36.	Eridanus, *Fluvius,*	Eridanus, *the River.*
37.	Lepus,	The Hare.
38.	Canis Major,	The Great Dog.
39.	Canis Minor,	The Little Dog.
40.	Argo Navis,	The Ship.
41.	Hydra,	The Hydra.
42.	Crater,	The Cup.
43.	Corvus,	The Crow.
44.	Centaurus,	The Centaur.
45.	Lupus,	The Wolf.
46.	Ara,	The Altar.
47.	Corona Australis,	The Southern Crown.
48.	Piscis Australis,	The Southern Fish.

The constellations added by Hevelius are the following:—

1.	Antinous,	Antinous.
2.	Mons Menelai,	Mount Menelaus.
3.	Asterion et Chara,	The Greyhounds.
4.	Camelopardalus,	The Giraffe.
5.	Cerberus,	Cerberus.
6.	Coma Berenices,	Berenice's Hair.
7.	Lacerta,	The Lizard.
8.	Lynx,	The Lynx.
9.	Scutum Sobieski,	Sobieski's Shield.
10.	Sextans,	The Sextant.
11.	Triangulum,	The Triangle.
12.	Leo Minor,	The Little Lion.

The constellations added by Halley in the southern hemisphere are,—

1.	Columba Noachi,	Noah's Dove.
2.	Robur Carolinum,	The Royal Oak.
3.	Grus,	The Crane.
4.	Phœnix,	The Phœnix.
5.	Pavo,	The Peacock.
6.	Apus, *Avis Indica,*	The Bird of Paradise.
7.	Apis, *Musca,*	The Bee or Fly.
8.	Chamæleon,	The Chameleon.

One of the most important objects of practical astronomy is the formation of catalogues of the fixed stars, in which their positions are determined for a given epoch; for it is only by means of registered observations that the state of the heavens can be compared at different times, and any changes which take place be detected. The apparent place of a star is easily determined by observation; but in order to render such observations available for the purposes of comparison, the mean place of the observed star must be computed and reduced to a given epoch; and this reduction, which involves a knowledge of the precession, nutation, aberration, and in general of all the motions which affect the star's apparent place, is only accomplished by a laborious process of calculation. Theoretical Astronomy

The principal catalogues of the stars which we possess are the following:— Catalogues of stars.

Ptolemy's catalogue, which contains 1022 stars. The positions are referred to the ecliptic, and the longitudes are for the year 137 of our era. It is supposed that the greater part of the observations on which it is founded were made and computed by Hipparchus 267 years before, and that Ptolemy merely reduced them to his epoch by adding to each of the longitudes 2° 40′, which, according to him, was the amount of the precession of the equinoxes in that interval. This catalogue forms part of the Almagest.

The catalogue of Ulugh Beigh, containing 1017 stars.

Tycho's catalogue, which contains only 777 stars, in 45 constellations.

Riccioli's catalogue, which contains 1468 stars. Part of it, however, was merely copied from more ancient catalogues.

Bayer's catalogue, containing 1762 stars, in 72 constellations. It was published in his *Uranometria* in 1603. The third edition of this work appeared at Ulm in 1661.

The catalogue of Hevelius, which contains 1888 stars, of which it gives the latitudes, longitudes, right ascensions, and declinations, for the year 1661. Published in his *Prodromus Astronomiæ* in 1690.

Flamsteed's catalogue, containing 2884 stars. Published in the *Historia Cœlestis Britannica* in 1725. A less perfect edition was given by Halley in 1712.

Catalogues of Lacaille.—The first of these, published in his *Astronomiæ Fundamenta,* contains 397 stars; the second, which is given in his *Cœlum Australe Stelliferum,* contains 1942 of the stars in the southern hemisphere; and the third, which was reduced from his observations by the celebrated Bailly, contains the places of 515 zodiacal stars.

Mayer's catalogue, containing 998 zodiacal stars. It appeared in his *Opera Inedita,* Göttingen, 1775, and was reprinted in the *Connoissance des Tems* for 1778.

Bradley's catalogue, containing 587 stars. This was published in the first volume of his observations, edited by Hornsby, in 1798. The positions of 389 stars, calculated from Bradley's observations, had been given by Mason in the *Nautical Almanack* in 1773. Bradley's observations extended to 3000 stars, but the greater part of them remained useless to astronomy till they were reduced and made the subject of discussion by Bessel in his *Fundamenta Astronomiæ,* Regiomonti, 1818.

Maskelyne's catalogue of 36 stars.

Cagnoli's catalogue, containing 501 stars. Published in the *Memoirs of the Italian Society.*

Bode's catalogue, which contains 17,240 stars, reduced from the observations of various astronomers.

Piazzi's catalogue, which contains 6748 stars, reduced to the year 1800. In 1814 Piazzi published a new catalogue, comprising 7646 stars.

Zach's catalogue, inserted in his *Tabulæ speciales Aberrationis et Nutationis,* Gothæ, 1806.

Theoretical Astronomy

Catalogue of the Astronomical Society of London, containing 2881 stars, published in the second volume of their *Memoirs*. Almost all the stars comprised in this catalogue are to be found in the catalogues of Bradley or Piazzi, from which they have been reduced to the year 1830.

In addition to the above, the records of great masses of observations may be found in the *Philosophical Transactions*, the *Connoissance des Tems*, and the various astronomical and scientific Journals. Lalande has registered in the *Memoirs of the Academy of Paris*, and his *Histoire Céleste*, the positions of no fewer than 50,000; and Bessel, of the Königsberg Observatory, who continues to explore the heavens with unabated zeal, has already examined an equal number. Astronomers are now aware of the importance of extending their researches to the most minute sidereal objects. (See Supplement.)

Sect. II.—*Of the Parallax, Distance, Magnitude, and Number of the Fixed Stars.*

The fixed stars being the points of departure from which all the celestial motions are estimated, one of the first objects in astronomy is to determine the amount and law of all the minute variations of position, real or apparent, to which they are subject. One of the most obvious consequences of the hypothesis of the annual motion of the earth is the existence of an annual parallax of the stars; but on account of the enormous distances of these bodies, this effect of the earth's motion is so small that it cannot be easily measured; and there are even now very few cases in which, with the utmost refinements of methods and instruments, a measurable parallax has been detected. The longest line which nature has furnished us with the means of actually measuring, is the circumference of our own globe. From this geometry teaches us how to find its diameter; and the diameter we employ as a scale with which to compare the distances of the sun and moon, and the other bodies of the solar system. But experience shows us that this scale, large as it is in our conceptions, is only an insensible point in comparison of the distances of the fixed stars. Astronomy has furnished us with another base, about 24,000 times longer than the former, or above 190 millions of miles. This is the diameter of the earth's orbit, which is most conveniently used for expressing the distances of the planets and comets from the sun. Yet even this line is in general insensible when compared with the distances of the stars; for, on observing the same star from its two extremities, at the end of six months, no variation whatever is perceptible in the star's position, after the proper corrections have been made for the small effects produced by different and known causes. The limits of the errors of modern observations cannot well be supposed to exceed 1″. It follows, therefore, that, seen from the distance of the fixed stars, the diameter of the ecliptic, which exceeds 190 millions of miles, subtends an angle of less than 1″. Had the annual parallax exceeded this small quantity, it could scarcely have escaped the multiplied efforts that have been made to detect it, not only by Bradley, whose observations, undertaken for the express purpose of determining the parallax of the stars, conducted him to the grand discoveries of the aberration and nutation, but also by other observers furnished with the more delicate instruments of the present day; and particularly the observations made with the splendid instruments of the Royal Observatory of Greenwich. A long controversy was carried on, extending from the year 1810 to 1824, between Dr Brinkley and Mr Pond, on the subject of the annual parallax of some of the brightest stars, Brinkley asserting that he had found large parallaxes, and Pond denying the existence of any measurable parallaxes. Brinkley's conclusions are now generally acknowledged to have been erroneous. Brinkley did not observe any parallax in the case of the stars of the constellation *β Cygni*, some of which, having a very sensible proper motion, may, with great probability, be considered as being at a less distance from the earth; but in *Wega* (α Lyræ) he found a parallax of 1″·13, and one of 1″·42 in the star *Altair*, in Aquilæ. Bradley supposed the parallax of Sirius to amount to 1″. These facts are, however, disproved by other eminent observers. In a series of 14 stars Struve found the parallax to be negative; that is, the small change of position which the observations seemed to indicate was in a direction contrary to what it would have been if it had arisen from the annual motion of the earth. Mr Pond, the Astronomer Royal, thought the probable value of the parallax could not exceed 0″·018, a quantity so extremely minute as to be altogether lost in the uncertainties of instrumental errors, and the errors of refraction, which are at least 20 times greater.

Theoretical Astronomy

Let us concede for a moment the disputed parallax of 1″, and inquire what must be the corresponding distance of the star. The semidiameter of the terrestrial orbit being taken at 95 millions of miles, the distance of a star whose parallax is 1″ will be expressed by $\frac{1}{\text{sin. } 1''} \times 95000000 = 206264 \times 95000000 = 19{,}595{,}080{,}000{,}000$, or about 20 trillions of English miles. To assist the imagination in forming some idea of this almost inconceivable distance, we may calculate that a ray of light which darts from the sun to the earth in the space of 8 min. 7 sec., would require 206264 × 8 min. 7 sec., or 3 years and 216 days, to reach us from the star. A spider's thread before the eye of a spectator placed at the same distance would suffice to conceal the orbit of the earth; and the breadth of a hair would blot out the whole planetary system. But a star having a parallax of 1″ is at a moderate distance in comparison of innumerable others, in which no parallactic motion whatever can be distinguished. Supposing the distance of one of these to be only a thousand times greater, a ray of light darted from it would travel between 3000 and 4000 years before it reached the earth; and if the star were annihilated by any sudden convulsion, it would appear to shine in its proper place during that immense period, after it had been extinguished from the face of the heavens. Pursuing speculations of this kind, we may conceive, with Huygens, that it is not impossible that there may exist stars placed at such enormous distances, that their light has not yet reached the earth since their creation.

Magnitude of the stars.

When viewed with the naked eye, the magnitudes of the stars appear to be very different,—a circumstance which may be attributed either to a real diversity of brightness, or, which is more probable, to the great differences in their distances. The sensible magnitudes which they exhibit when viewed in this manner are owing only to the numerous reflections of the rays of light from the aerial particles surrounding the eye; as is proved by looking at them through a long tube, which prevents any rays from reaching the eye excepting those which come directly from the star. In the telescope their dimensions are entirely inappreciable: the greater the power with which they are viewed, the smaller are their apparent diameters, because they are then more completely divested of the effects of irradiation. A star having a diameter of 1″, and an annual parallax of 1″, would be more than a million of times larger than the sun. Nevertheless, Sir W. Herschel assures us, that, by means of the great powers which his telescopes carried, he had seen the disks of some stars perfectly round, and had even succeeded in measuring

Theoretical Astronomy.

their apparent diameters. He found the diameter of *Wega* to be $\frac{1}{3}''$, that of *Aldebaran* $1''{\cdot}5$, and that of *Capella* $2''{\cdot}5$. Supposing the measurement accurate, and the annual parallax of this last not to exceed $1''$, its volume would be equal to 20 million times that of the sun.

Number of the stars.

With regard to the number of the stars, it is altogether impossible to form any satisfactory conjecture. Of those which are visible to the naked eye, the number does not, probably, at any time, exceed 1000, although, from the effect of their twinkling, and the confused manner in which they are seen, one is apt to suppose them to be much more numerous; but in the telescope they are prodigiously multiplied. Within the limits of a space extending 15° by 2°, Herschel counted no fewer than 50,000. In the single constellation of the Pleiades, instead of 6 or 7, which can be distinguished by the unassisted vision, Hooke, with a telescope of 12 feet, counted 78; and in telescopes of greater power the number appears to be vastly larger. Although, by reason of their very unequal distribution, no accurate estimate can be formed of the number contained in the whole sphere by the examination of any small portion of it, yet there is some reason to conclude that there cannot be less than 75 millions of stars altogether visible in a good telescope. Baron Zach estimates that there may be at least a thousand millions of stars in the entire heavens, without reckoning (what may probably exist) opaque bodies which cannot be perceived, and stars whose light has been extinguished. It is, however, evident that all estimates of this sort have no other limit than such as is imposed by the imagination. If an observer could be transported to the remotest star visible in his telescope, he would probably see extending before him in the same direction, a firmament equally rich and splendid as that which he beholds from our own insignificant planet.

Sect. III.—*Of the Proper Motions of the Stars.*

In Chap. II. four different causes of apparent motion with regard to the stars have been explained; namely, the precession of the equinoxes, the nutation of the earth's axis, the secular diminution of the obliquity of the ecliptic, and the aberration of light; all which are occasioned by the various motions proper to the earth, and for that reason are called apparent motions. But if, after due allowance has been made for the effects produced by them, it should happen that the observed place of any star, or number of stars, does not correspond with former observations, a new and peculiar motion would be indicated, which must be explained by a new hypothesis. Now there are obviously two ways of accounting for such a phenomenon, namely, a parallactic motion and a proper motion, from either of which the observed variation of position may result. It has already been shown that the annual parallax, or that apparent alteration in the places of the fixed stars which might be expected from the motion of the earth in its orbit, is insensible; but we may suppose, and indeed observation has even rendered it probable, that the sun, accompanied by his whole train of planets and comets, is in motion in space; and if this is the case, the stars must appear to change their relative situations as soon as the sun has described a space bearing a sensible ratio to their distance. The resulting motion would thus partake of the nature of parallax, and is hence termed parallactic. The other method of accounting for any observed alteration in the mutual position of the stars, is to ascribe to them a proper motion, instead of supposing them to be absolutely fixed. On this supposition the motion is real; yet it may happen that the observed changes of position result from the combined effects of a real and parallactic motion. The effects of these motions are in their nature sufficiently distinct, although, on account of the extremely minute quantities to be determined, and the uncertainty that still exists as to the exact amount of some of the apparent motions with which they are blended, it may for centuries to come be found impossible to separate them. If all the stars forming a group, or situated in the same quarter of the heavens, appear to recede from or approach to each other, their motions may with reason be ascribed to the translation of the solar system in space, and consequently be parallactic: but if, on the contrary, some appear stationary, while others appear to move in different directions, the phenomena will indicate a real change in the positions of the stars.

Theoretical Astronomy.

From the analogy of our own system we are naturally induced to extend the principle of gravity to the sphere of the stars, and to suppose, as a necessary consequence, that none of the celestial bodies are in a state of absolute repose. Their mutual attraction must communicate to them a motion which would end in uniting them all in the same mass unless it were counteracted by a centrifugal force: hence the stars are supposed to move about distant centres in orbits analogous to those of the planets. But if the stars are not absolutely at rest in space, their motions must be extremely slow, inasmuch as the actual state of the heavens corresponds entirely with the descriptions that have been given of it by Hipparchus and Ptolemy. Ptolemy has transmitted to us a great number of observations on the relative situations of the fixed stars, made by Hipparchus, whose method was to observe those which are situated in an arc of the same circle, or which can be intersected by the same straight line; and he assures us that he himself, after an interval of 260 years, could perceive no alteration. In order to furnish posterity with the means of pursuing similar inquiries, Ptolemy added the positions of many other stars determined by his own observations; and we owe to his labours the certain knowledge that the relative positions of the stars, notwithstanding the numerous displacements of the ecliptic and equator, are at present nearly the same as they were 2000 years ago. The ancient observations were, however, of too rude a nature to admit of any satisfactory conclusion being deduced from them respecting the minute quantities in question. The accurate instruments of the present day have enabled observers to remark some changes of position too decided to admit of doubt; hence astronomers have inferred a proper motion in several stars, as well as a translation of the sun and the planets in space. From the comparison of a great number of observations, Sir W. Herschel was of opinion that many of the proper motions might be explained by supposing the solar system to have a motion directed towards the star λ in the constellation Hercules. Bessel, having subjected to a rigorous comparison a much greater number of the proper motions indicated by comparing the catalogues of Bradley, Mayer, Piazzi, &c. arrived at the conclusion that many points might be assigned in the sphere, some of them even diametrically opposite to each other, situated in the direction of those motions; but that, in whatever direction the sun is supposed to move, so many proper motions will remain unaccounted for, that there is no reason for preferring one point to another. It has since been demonstrated, however, by astronomers, that Bessel's conclusion was erroneous, and that Herschel's idea was correct. The conspicuous proper motions of the stars which have hitherto been remarked are subject to an assignable law, and are not directed to arbitrary points in space; and it is only after eliminating the effects of the solar motion, that the real proper motions can be inferred. It is, how-

Theoretical Astronomy

ever, on the whole, probable that they are due, in part at least, to a real displacement of the stars, and not to a general translation of the solar system.

As early as the beginning of the present century, astronomers had detected proper motions in a great number of stars, the rates of which they inserted in their catalogues along with those of the precession; but great discrepancies existed in their conclusions. Baron Zach, comparing Maskelyne's observations of the right ascensions of the Greenwich stars, reduced to 1802, with those of Bradley, reduced to 1760, found results which differ from those of Maskelyne himself, not only in *amount*, but in several instances even in the *direction* of the supposed proper motions. For example, the proper motions (in right ascension) of *γ Pegasi*, *α Ceti*, *Rigel*, *Sirius*, *Spica*, *γ* and *β Aquilæ*, *α Cygni*, *α Aquarii*, and *α Pegasi*, are all *positive* according to Zach, while Maskelyne considered them as being all *negative*. Such was the uncertainty respecting the proper motions even of the Greenwich stars, which, by reason of the frequent observations they had undergone, and the rigorous scrutinies to which they had been subjected, were probably those whose places had been the most accurately determined of any in the whole heavens. But the motions are so slow that they must remain, for a considerable number of years at least, blended with the errors of observation. The double star 61 *Cygni* is indeed demonstrated to have an annual proper motion of + 5″·06 in right ascension, and 3″·34 in declination; but in general the rates are confined within much narrower limits, and appear to amount only to a fraction of a second. The number of stars in which this proper motion has been supposed to be observed is, as we have already noticed, very considerable. M. Bessel, by a comparison of 2959 stars out of Bradley's catalogue with the same stars in the catalogue of Piazzi, found that 425 of them had an annual proper motion, amounting to more than 0″·2, in the arc of a great circle. The following table, published by Mr Baily in the second volume of the Memoirs of the Astronomical Society, contains a list of all those stars observed by Bradley and Mayer, whose annual proper motions, according to Piazzi, as given in his catalogue, amount to 0″·5 either in right ascension or declination. The *positive* sign, in the column of declinations, denotes a motion towards the north, the *negative* a motion towards the south. The numbers prefixed are those of Flamsteed, unless when inclosed within a parenthesis, in which case they are those of Piazzi.

The proper motions of the stars are not susceptible of direct observation or measurement: they are only indicated by the minute differences which remain after applying to the observed position of any given star the corrections due to all the apparent motions with which we are acquainted. Thus, let M and M′ be the mean places of any given star

Theoretical Astronomy

at two different epochs, the interval between which is t years; P the annual precession of the equinoxes, and x the annual motion of the star in right ascension. It is obvious that x will be given by the formula

$$x = \frac{M - M'}{t} - P;$$

so that the value of x, or the amount of the proper motion, is dependent not only on the accuracy of the observations, and on the computations from which M and M', the mean places of the star, have been deduced, but also on the quantity P, which is calculated by a method of approximation not entirely exact. For all these reasons it is easy to see that the determination of the proper motions must be attended with considerable uncertainty, and that hundreds, probably thousands, of years will be required to develope their rates and directions, and assign the distant centres round which they are performed. (See Supp.)

Sect. IV.—*Of Variable and Double Stars, Nebulæ, and the Milky Way.*

The periodical variations of brilliancy to which some of the fixed stars are subject, may be reckoned among the most remarkable of the phenomena exhibited by those bodies. Several stars, formerly distinguished by their splendour, have entirely disappeared; others are now conspicuous which do not seem to have been visible to the ancient observers; and there are some which alternately appear and disappear, or of which the light at least undergoes great periodic variations. Some seem to become gradually more obscure, as δ in the *Great Bear;* others, like β in the *Whale*, to be increasing in brilliancy. Some stars have all at once blazed forth with great splendour, and, after a gradual diminution of their light, have again become extinct. The most remarkable instance of this sort is that of the star which appeared in 1572, in the time of Tycho. It suddenly shone forth in the constellation Cassiopeia with a splendour exceeding that of stars of the first magnitude, even of Jupiter and Venus at their least distances from the earth, and could be seen with the naked eye on the meridian in full day. Its brilliancy gradually diminished from the time of its first appearance, and at the end of sixteen months it entirely disappeared, and has never been seen since. During the whole time of its apparition its place in the heavens remained unaltered, and it had no annual parallax; its distance was consequently of the same order as that of the fixed stars. Its colour, however, underwent considerable variations. Tycho describes it as having been at first of a bright white; afterwards of a reddish yellow, like Mars or Aldebaran; and, lastly, of a leaden white, like Saturn. Another instance of the same kind was observed in 1604, when a star of the first magnitude suddenly appeared in the right foot of Ophiuchus; it presented phenomena analogous to the former, and disappeared in like manner after some months. Kepler wrote a book on this singular apparition. These instances sufficiently prove that the stars are subject to great physical revolutions.

A great number of stars have been observed whose light seems to undergo a regular periodic increase and diminution, and these are properly called *variable* stars. One in the *Whale* has a period of 334 days, and is remarkable for the magnitude of its variations. From being a star of the second magnitude, it becomes so dim as to be seen with difficulty through powerful telescopes. Some are remarkable for the shortness of the period of their variation. *Algol* has a period of between two and three days, δ *Cephei* one of $5\frac{1}{3}$ days, β *Lyræ* one of $6\frac{2}{3}$ days, μ *Antinoi* one of 7 days. The regular succession of these variations precludes the supposition of their being occasioned by a real or permanent destruction of the stars; neither can they be supposed to arise from a change of distance; for as the stars invariably retain their apparent places, it would be necessary to suppose that they approach to and recede from the earth in straight lines,—an hypothesis which is at least extremely improbable. The most probable supposition is, that the stars revolve, like the sun and planets, about an axis; and that the surfaces of the variable stars are unequally covered with dark spots, or unequally fitted to emit light; whence their dark sides will be turned towards us after certain intervals by the effect of rotation. In this way Newton accounted for the phenomena. Other astronomers have devised different explanations. Maupertuis supposed that the figure of the stars is not globular, but flat, and that the variations of brilliancy depend on the angle which their flat sides make with the visual ray,—an angle which will be constantly varying if the stars are endowed with a rotatory motion. Others, again, have imagined that the partial obscurations of the stars may be occasioned by their being eclipsed by opaque bodies or planets revolving round them.

Theoretical Astronomy

Multiple stars.

On examining the stars with telescopes of considerable power, many of them are found to be composed of two or more stars placed contiguous to each other, or of which the distance subtends a very minute angle. This appearance is probably in many cases owing solely to the optical effect of their position relative to the spectator; for it is evident that two stars will appear contiguous if they are placed nearly in the same line of vision, although their real distance may be immeasurably great. There are, however, many instances in which the angle of position of the two stars varies in such a manner as to indicate a motion of revolution about a common centre; and in this case the two stars form a binary system, performing to each other the office of sun and planet, and connected together by gravity or some equivalent principle. The recent observations of Herschel, Dawes, South, and Struve, have placed this fact beyond doubt. Motions have been detected so rapid as to become measurable within very short periods of time; and at certain epochs the satellite or feebler star has been observed to disappear, either on passing behind or before its primary, or by approaching so near to it that its light has been absorbed by that of the other. The most remarkable instance of a regular revolution of this sort is that of the double star ξ *Ursæ Majoris*, in which the angular velocity is $6°{\cdot}4$ annually, so that the two stars complete a revolution about one another in the space of 60 years; and above three fourths of a circuit have been already described since its discovery in 1781. The double star p *Ophiuchi* presents a similar phenomenon, and the satellite has a motion in its orbit still more rapid. α *Castoris*, γ *Virginis*, ζ *Cancri*, ξ *Bootis*, δ *Serpentis*, and that remarkable double star 61 *Cygni*, together with several others, exhibit similar variations in their respective angles of position.

The examination of double stars was first undertaken by Sir W. Herschel, with a view to the question of parallax; for it is evident, and indeed had been remarked by Galileo, that the apparent distance of two stars which are very near each other will vary with the position of the earth in its orbit, unless they are both so remote that, in comparison of their distance from the earth, the diameter of the terrestrial orbit is insensible. His attention was, however, soon arrested by the new and unexpected phenomena which these bodies presented. Sir W. Herschel observed in all 2400 of them. Messrs South and Herschel have given a catalogue of 380 in the Transactions of the

Theoretical Astronomy.

Royal Society for 1824, and South added 458 to the list in the volume for 1826. Mr Herschel has published three series of observations in the Memoirs of the Astronomical Society, containing altogether 1000 double stars; and the catalogue of M. Struve of Dorpat contains 3063 of the most remarkable. The object of these catalogues is not merely to fix the place of the star within such limits as will enable it to be easily discovered at any future time, but also to record a description of the appearance, position, and mutual distances, of the individual stars composing the system, in order that subsequent observers may have the means of detecting their connected motions, or any changes with which they may be affected. M. Struve has also taken notice of 52 triple stars, among which No. 11 of the *Unicorn*, ζ of *Cancer*, and ξ of the *Balance*, appear to be ternary systems in motion. Quadruple and quintuple stars have likewise been observed, which also appear to revolve about a common centre of gravity. Every region of the heavens furnishes examples of these curious phenomena, especially those which abound in stars; though M. Struve remarks that some parts of the milky way contain very few, while others present them in great abundance.

Some of the double stars present curious instances of contrasted colours, and generally assume the complementary tints,—a circumstance which, Mr Herschel thinks, may be owing in some degree, at least in cases where red and green, yellow and blue stars are combined in a double star, to the influence of optical deception. "When I first observed," says that ingenious philosopher, "the double star No. 881, A. 19 hours 8 minutes 56 seconds, P. D. 95° 45′ 33″, I remarked it as a case of contrasted colour, the large star being ruddy, and the small one blue. But on closer attention I perceived the small star itself to be double; yet each of the two very minute stars of which it consists appeared equally blue while the eye continued under the influence of the large one; but when this was withdrawn from the field, they appeared of no particular colour, but just like other small stars in the neighbourhood. It may be remarked further, too, that yellow stars are, generally speaking, accompanied by blue small ones, blue being the complementary tint of yellow; but when the large star has an excess of red rays, the blue verges to green, as it ought on the hypothesis of contrast. A most remarkable instance is that of No. 895 (Struve's catalogue), A. 6 hours 12 minutes, P. D. 84° 12′, in which the large star is of a full ruby red, and the smaller one of a fine green, but which colour it also loses when the large star is concealed behind the cross of the wires." (*Memoirs of the Astronomical Society*, vol. iii. p. 186.)

Nebulæ.

The *Nebulæ*, so called from their dim cloudy appearance, form another class of objects which furnish matter for curious speculation and conjecture respecting the formation and structure of the sidereal heavens. When examined with a telescope of moderate powers, the greater part of the nebulæ are distinctly perceived to be composed of clusters of little stars, imperceptible to the naked eye, because, on account of their apparent proximity, the rays of light proceeding from each are blended together, through the effects of irradiation, in such a manner as to produce only a confused luminous appearance. In others, however, no individual stars can be perceived, even through the best telescopes; and the nebula exhibits only the appearance of a self-luminous or phosphorescent patch of matter in a highly dilated or gaseous state; though it is possible that even in this case the appearance may be owing to a congeries of stars so minute, or so distant, as not to afford singly sufficient light to make an impression on the eye. In some instances the nebula presents the appearance of a faint luminous atmosphere, of a circular form, and of large extent, surrounding a star of considerable brilliancy. One of the most remarkable nebulæ is that which is situated in the sword-handle of Orion. It was discovered by Huygens in 1656, and described and figured by him in his *Systema Saturnium*. Since that time it has been examined and described by various observers, particularly Fouchy, Mairan, Le Gentil, and Messier, who have given engravings of it; and if any trust can be placed in their descriptions of so indistinct and difficult an object, it must have undergone great changes in its form and physical appearances. Unfortunately, however, no satisfactory inference can be drawn from the comparison of the different descriptions; for it is found that the same nebula, viewed on the same night with different telescopes, presents appearances so different as to be scarcely recognizable as the same object. The effects of atmospherical variations also cause great differences in its appearance, even when it is viewed through the same telescope at different times; so that it is scarcely possible that any two observers will be found to agree in their delineations of its outline. Sir J. Herschel, in the second volume of the Memoirs of the Astronomical Society, has given a detailed description of this nebula as it appeared in his twenty feet reflector in 1824, together with a drawing which, on account of the superiority of his telescope, is probably a much more correct representation of the object than any which previously existed. Fig. 108 is copied from that drawing. Of that portion of the nebula which he calls the Huygenian region Mr Herschel gives the following account: "I know not how to describe it better than by comparing it to a curdling liquid, or a surface strewed over with flocks of wool, or to the breaking up of a *mackarel sky* when the clouds of which it consists begin to assume a cirrous appearance. It is not very unlike the mottling of the sun's disk, only (if I may so express myself) the grain is much coarser, and the intervals darker; and the flocculi, instead of being generally round, are drawn out into little wisps. They present, however, no appearance of being composed of small stars, and their aspect is altogether different from *resolvable nebulæ*. In the latter we fancy that we see stars, or that, could we strain our sight a little more, we should see them; but the former suggests no idea of stars, but rather of something quite distinct from them."

Theoretical Astronomy.

Plate LXXXVIII

Another very remarkable nebula is that in the girdle of Andromeda, which, on account of its being visible to the naked eye, has been known since the earliest ages of astronomy. It was re-discovered in 1612 by Simon Marius, who describes it as having the appearance of a candle seen through horn, that is, a diluted light, increasing in density towards a centre. Le Gentil mentions that its figure had appeared to him for many years round, but that in 1757 it had become oval. He also remarks that its light was perfectly uniform in all parts,—a fact which is quite at variance with its present appearance, and which, if true, argues that the nebulous matter is in a rapid state of condensation. "At present," says Sir J. Herschel, in the volume above referred to, "it has not, indeed, a star or any well-defined disk in its centre; but the brightness, which increases by regular gradations from the circumference, suddenly acquires a great accession, so as to offer the appearance of a nipple, as it were, in the middle, of very small diameter (10″ or 12″), but totally devoid of any distinct outline, so that it is impossible to say precisely where the nucleus ends and the nebula begins. Its nebulosity is of the most perfect milky, absolutely irresolvable kind, without the slightest tendency to that separation

Theoretical Astronomy: Supplement

into flocculi above described in the nebula of Orion; nor is there any sort of appearance of the smallest star in the centre of the nipple. This nebula is oval, very bright, and of great magnitude, and altogether a most magnificent object."

Sir W. Herschel, who devoted himself to the examination of every uncommon appearance in the sidereal heavens, has given catalogues of 2000 nebulæ and clusters of stars discovered by him, and has shown that the nebulous matter is distributed through the immensity of space in quantities inconceivably great, and in separate parcels of all shapes and sizes, and of all degrees of brightness between a mere milky appearance and the condensed light of a fixed star. Finding that the gradations between the two extremes were tolerably regular, he thought it probable that the nebulæ form the materials out of which nature elaborates suns and systems, and conceived that, in virtue of a central gravitation, each parcel of nebulous matter becomes more and more condensed, and assumes a rounder form; that from the eccentricity of its shape, and the effects of the mutual gravitation of its particles, it acquires gradually a rotatory motion; that the condensation goes on increasing till the mass acquires consistency and solidity, and all the other characters of a comet or planet; that by a still further process of condensation the body becomes a real star, self-shining; and that thus the waste of the celestial bodies, by the perpetual diffusion of their light, is continually compensated and restored by new formations of such bodies, to replenish for ever the universe with planets and stars. (See the *Philosophical Transactions* for 1811.) These hypotheses or conjectures give no doubt a mechanical reason for the formation of stars, but the answer to them is exceedingly obvious. Has any instance as yet been observed of a nebula being succeeded by a star, or cluster of stars, or even of becoming so much more condensed as absolutely to change its form? Till a change of this sort has been observed, the inferences are drawn from analogies too slender to entitle them to be regarded as any thing more than mere fancies and speculations. Even if every link in the chain were perfect, and the gradation distinctly traced from the most diffuse nebula to the most compact star, the facts would still be insufficient to warrant the conclusion that the celestial matter had actually undergone a transition from the nebulous to the stellar state, or that any star or nebula in the heavens ever existed in a state different from its present. Though there is little reason to hope that we shall ever obtain a full knowledge of the mysterious processes which the great Architect of the universe has employed in the formation of the celestial bodies, yet a long series of observations with such instruments as are now constructed may lead to the detection of changes sufficiently indicative of the nature of the forces by which they are produced. These cosmological speculations, however, it may be well to remark, are not of the slightest value to astronomy.

Theoretical Astronomy: Supplement

Milky Way.

That great luminous tract which encompasses the sky like a girdle, and is called the *Galaxy* or *Milky-Way*, is supposed by Sir W. Herschel to be a nebula of which the sun forms one of the component stars; and hence it appears immensely greater than other nebulæ only in consequence of our situation with respect to it, and of its greater proximity to our system. On examining any part of it with a good telescope, we perceive a prodigious multitude of small stars, whose blended light occasions the whitish appearance which forms so remarkable an object in the heavens. Yet notwithstanding the apparent contiguity of the stars which crowd the galaxy, it is certain that their mutual distances cannot be less than a hundred thousand times the radius of the terrestrial orbit. From this we may attempt to form some notion of the inconceivable distances of the other nebulæ, some of which, probably not inferior in magnitude to the milky-way, appear only as small luminous patches in the telescope.

Trans.* 1784; Pigott, *Phil. Trans.* 1785, 1797; Lemonnier, *Mém. Acad. Par.* 1789; Lalande, *Astronomie* (885); Herschel, *Phil. Trans.* passim. (T. G.)

Supplement to Part II.

Since the last revision of the article Astronomy in this work, the discoveries in many of the branches of the science have been so various and of so much importance, that it would have been useless to attempt their incorporation in the body of the work without a total alteration of its construction. It has been, therefore, judged more convenient, as well as more useful, to add in a supplement such discoveries and improvements as have had an undoubted influence on the science in its present condition, and which hold out hopes of still greater extension for the future.

We shall preserve the same order as that used in the preceding part devoted to *Theoretical* Astronomy, and describe as briefly as possible the chief additions which have been made to the respective departments of the Planetary, Cometary, and sidereal branches of the subject.

CHAP. I.

OF THE SUN.

Sect. I.—*Of the Motion of the whole Solar System in Space.*

It has been previously mentioned (vol. iii. p. 807) that the idea of a proper motion of the sun had been embraced by Sir W. Herschel, but had been rejected as improbable by Bessel and other astronomers. The fact, however, of the existence of this motion has been now rendered incontestible by the independent labours of several astronomers, and we propose to give briefly the grounds of their several determinations.

First, with regard to theory, let us imagine that the sun has a motion (carrying, of course, the earth with it) which, for the small interval of time included by our modern observations which are of sufficient accuracy to decide the point, may be considered as uniform and rectilinear, towards a point of the heavens denoted by right ascension A and declination D. It is evident, in the first place, that the general effect of such a motion would be to produce an apparent displacement of all the stars in the heavens of such a nature as to increase the apparent angular distances of all stars towards which the motion is described, and to diminish the apparent distances of all those in the opposite quarter of the heavens. With regard to the right ascensions of all stars, then, the effect would be to produce an apparent proper motion in that element, such that the right ascensions to the left of the point towards which the sun is moving would be increased, and those to the right would be diminished; while those lying in the meridian of the solar motion would remain unaltered. Similarly with regard to the stars lying in the latter plane, the north polar distance of all to the north of the point of solar motion would be diminished, while all to the south of it would be increased.

To determine accurately the amount of apparent motion of any star in right ascension and declination, let α and δ be the right ascension and declination of any star at a linear distance r from the sun or earth. Then, if the line joining the earth or sun, and the star, make with the line of direction of the supposed motion, an angle θ; and if, in the unit of time, the linear solar motion be a, the angle of apparent displacement of the star in this plane will be $\frac{a}{r} \sin \theta$. If, now, we imagine the

Theoretical Astronomy: Supplement

spherical triangle formed by the great circles joining the north pole of the heavens, the apex of solar motion, and the star, its three sides will be $90° - D$, $90° - \delta$, and θ; and the angle opposite to θ will be $\alpha - A$. From this it may be readily shewn that the apparent motion in R. A. is $+\frac{a}{r}\frac{\cos. D \sin. (\alpha - A)}{15 \cos. \delta}$ (expressed in time), and the motion in declination (northwards) is $+\frac{a}{r}\left\{\sin. D \cos. \delta - \cos. D \sin. \delta \cos. (\alpha - A)\right\}$. These, then, are the formulæ by which the proper motions of the stars, when deduced from comparison of observations made at distant epochs, are to be tested; and, assuming that the *solar motion does really exist*, and that, on the whole, the proper motions of the stars are to be attributed to it, the most probable values of A and D are to be deduced; and it is evident that, since there is antecedent probability of the *reality* of the motions of many of the stars, the most probable values can only be determined by the use of a tolerably large catalogue in all parts of the heavens, so that their *real* proper motions having no determinate direction, the effects will be eliminated, or nearly so, in the final result. Another difficulty arises from the circumstance that the formulæ involve the distances of the stars which, except in a very few exceptional cases, are totally unknown. This can only be obviated either by assuming, with Argelander, that, on the average, stars having the greatest proper motions are nearest to the sun; or, by introducing, with Otto Struve, some empirical law of distance derived from the apparent magnitudes. Both hypotheses are precarious; but it is likely that, with either, the average result for the position of the apex of solar motion, deduced from a large catalogue of proper motions, will be tolerably correct; and it is also not improbable that in large numbers of stars the distances will so far agree with the law of apparent magnitudes, as to give a result for the actual amount of solar motion (based on the few cases of distances actually known) not very far distant from the truth.

The first astronomer who successfully attempted a solution of the problem was Argelander, in a paper published in 1837 in the *Mémoires presentées par divers Savans* of the Imperial Academy of St Petersburg. The proper motions employed are those derived from his own catalogue of 560 stars observed at Abo, by comparison with Bradley's observed places, as given in Bessel's *Fundamenta*. The only peculiarity which we have space to notice in Argelander's treatment of the problem is, that, assuming stars with the greatest proper motions to be nearest to us, he divides them into three classes determined by the greatness of the proper motions, and deduces a separate result from each class. The final result which he deduces is, when reduced to 1800,

$$A = 259° 51'·8; \quad D = + 32° 29'·1.$$

In No. 398 of the *Astronomische Nachrichten*, Argelander gives a result obtained by Lundahl, based on a comparison of 147 stars of Pond's catalogue of 1112 stars with the *Fundamenta*, each of the stars having an annual proper motion not less than 0″·09. The result arrived at is for 1792·5,

$$A = 252° 24'·4; \quad D = + 14° 26'·1.$$

The most important paper is that of M. Otto Struve, printed in the fifth volume of the *Petersburg Transactions* for 1842. The title of the paper is *Bestimmung der Constante der Precession mit Beruchsichtigung der eigenen Bewegung der Sonnensystems*, and for it the author received the gold medal of the Royal Astronomical Society in 1850. The investigation is grounded on the proper motions of about 400 stars (chiefly double) observed at Dorpat; for determining the weights of his equations, he assumes that the distances of the stars are inversely as the apparent magnitudes; and for his final result he obtains, as the most probable values of A and D for 1790,

$$A = 261° 21'·8; \quad D = + 37° 36'·0.$$

And, by combining his observations with those of Argelander and Lundahl with proper weights he obtains, finally, for 1792·5,

$$A = 259° 9'·4; \quad D = + 34° 36'·5.$$

The most recent investigation of the direction of the solar motion is by Mr Galloway, printed in the *Philosophical Transactions* for 1847, Part I., and for which the royal medal was awarded to him. His object was to show whether the general *drift* of the southern stars indicated a motion of the sun towards the same point of the heavens as that indicated by the northern stars. For this purpose he employed the catalogue of 606 stars observed at St Helena by Mr Johnson, and the catalogue of 172 stars observed by Mr Henderson at the Cape of Good Hope; Mr Galloway's method of investigation is precisely the same as that of Argelander, excepting that he does not attempt to assign weights to his equations by any hypothesis whatever with regard to the distances of the fixed stars, considering that no greater probable accuracy could be obtained in his inquiry by the adoption either of Argelander's or of Otto Struve's assumption of the criterion of distance. The result which he obtains for the values of A and D is, for the epoch 1790,

Theoretical Astronomy: Supplement

$$A = 260° 0'·6; \quad D = + 34° 23'·4.$$

The essential identity of this position of the apex of solar motion, derived from the southern stars, with that deduced from three separate sets of northern stars, confirms the *fact* of the existence of this motion, and shows that we have arrived at a very close approximation to its direction. The investigation of Otto Struve has also shown that its amount (0″·3 in a year) is too large to be neglected in any future cosmical speculations. The subject is therefore one of very considerable importance, and must form the basis of any future inquiries respecting the connexion of our sun and planets with that sidereal system of which they form a part.

Section II.—*Of the time of rotation of the Sun, and the physical peculiarities of his surface.*

In the preceding part of this article, the method has been explained by which astronomers have determined, with various degrees of accuracy, the time of the sun's rotation, and the position of his equator with regard to the ecliptic, by means of observations of the spots which are frequently observed on his disk. The chief observations and investigations having this object in view, were made by Scheiner, Cassini, and Lalande, at epochs included between the years 1626 and 1776. Recently several attempts have been made to obtain results of greater accuracy, by M. Laugier, Dr Petersen, and Dr Böhm of Vienna. The dissertation of the last-named astronomer has been recently printed in vol. iii. of the *Denkschriften der Mathematisch-Naturwissenschriftlichen Classen* of the Academy of Sciences of Vienna; and this paper is well worthy of the attention of the student, from the elaborate care which has been bestowed upon the mathematical treatment of the subject, as well as for the excellence of the observations carried on for some years on which the results depend.

The results deduced by Dr Böhm are, for the epoch 1834·6:

Longitude of ascending node of sun's equator, $= 76° 46'·9$.
Inclination of sun's equator to ecliptic, . . $= 6° 56'·6$.
Time of sun's rotation, $= 25$ days 12 hours 30 minutes.

The times of rotation, according to M. Laugier and Dr Petersen, are respectively,

$$25^d\ 8^h\ 10^m, \text{ and } 25^d\ 4^h\ 30^m.$$

With regard to the physical peculiarities of the surface of the sun, some important additions have been recently made by Mr Dawes, by means of an eye-piece devised by himself, which enables the observer to examine minutely, and with comfort, any separate portion of the disk. Mr Dawes' apparatus is very simple, and consists of a metallic perforated slide (the perforations being of a different size for different purposes) which crosses the eye-tube at right angles, in place of the fixed bar; that is, in the plane of the focus of the object-glass. By this means the field of view can be rendered as small as is desired for examination of a minute portion of the solar disk, the only light and heat reaching the eye being those transmitted from that portion. This eye-piece has since been adopted by other astronomers, and Mr Dawes was rewarded almost immediately after its application by the discovery of two facts of considerable importance in the theory of the solar spots.

The first discovery relates to the existence of a stratum of comparatively faint luminosity, which he denominates a *cloudy stratum*, giving the impression of considerable depth below the second luminous stratum, which forms the *shadow* or *pen-*

Theoretical Astronomy: Supplement

umbra usually seen round the nucleus of a spot. This stratum appears to be not self-luminous, but of such a nature as to absorb a vast quantity of light and to reflect very little. The [illegible] presenting rather a mottled or cloudy surface, and occasionally some very small patches are very decidedly more luminous than the rest. In all spots of considerable size, a *black opening* is perceivable in the cloudy stratum, which is proved to be, if luminous at all, less so than our own atmosphere when illuminated by the direct rays of the sun.

The second curious fact discovered by Mr Dawes is that of the rotation of the spots. This phenomenon was seen remarkably in the case of a spot sketched on January 17 and January 23 of the year 1852; by which it became evident that in this interval the spot had rotated through 180°. If we accept the usual hypothesis, that the spots are vast disturbances in the atmosphere of the sun, revealing to us for a time part of his surface, what an idea does this present to us of the magnitude of the operations of nature in this stupendous globe! A mass of aeriform or gaseous fluid, whose diameter is frequently more than 100,000 miles, is agitated by a rotating storm similar probably to those which sometimes devastate the surface of our own planet. In the above instance, the mass must have taken about twelve days to complete a revolution; and therefore, though the angular velocity is moderate, yet the outer circle would be moving with the enormous velocity of about 600 miles per hour, a velocity in fact ten times greater than that of the fiercest hurricanes which have at times laid waste portions of the surface of the earth.

With regard to the *faculæ*, Mr Dawes has had opportunities of proving the correctness of Sir J. Herschel's supposition, that they are in reality great waves or undulations projecting beyond the general surface of the solar disk. He says, "The faculæ are best seen near the east and west edges of the sun's disk, where they give the impression of narrow ridges, whose sides are there presented to view. . . . . They are rarely seen as actual projections from the limb. On one occasion, however, I had an opportunity of observing a satisfactory confirmation of the idea that they are ridges or heapings up of the luminous matter. . . . . A large bright streak or facula was observed to run, as usual, nearly parallel to the sun's edge for some distance, and very near it; and then to turn rather abruptly towards the edge and pass over it. The limb was at this time very well defined; and, when it was most sharp and steady, the bright streak was seen to *project slightly beyond the smooth outline of the limb*, in the manner of a mountain ridge nearly parallel to the sun's equator."

Considerable information respecting the solar disk has been obtained by the organized observations of the total solar eclipses which occurred on July 8, 1842, and July 28, 1851. The former of these phenomena was admirably observed by Mr Baily at Pavia, and by Mr Airy at Turin, and detailed accounts of their observations and impressions are given in vol. xv. of the *Memoirs of the Royal Astronomical Society*, accompanied by drawings of the different phases of the eclipse. The attention of astronomers having been, by these and other accounts, directed to the extreme importance of observing with every possible accuracy the total eclipse of 1851, an organization was formed under the auspices of the British Association, and *Suggestions* were published previously, giving minute directions as to the observation of every possible phenomenon which might occur. The observations were remarkably successful, and the accounts of the British observers alone form the first part of vol. xxi. of the *Memoirs of the Royal Astronomical Society*.

An abstract of the results of the observations with regard to the points of greatest interest, such as "Baily's beads," usually seen on the breaking up of the last narrow annulus of light; the corona or faint ring of light which becomes visible when the moon is quite hidden; and the red or rose-coloured prominences which are then seen outside, and in contact with the black lunar disk, will be found in the *Annual Report of the Council of the Royal Astronomical Society*, for February 1852.

In looking for proximate causes of these phenomena, it would naturally occur to any inquirer to seek for their origin, either in the spots on the surface of the solar disk, or in the faculæ or wave-like ridges of light that are visible near the borders, and to this probable identification the attention of astronomers was directed previously to the eclipse of 1851. In particular, M. Schweizer, director of the Observatory of Moscow, took the precaution of having drawings carefully made of all the faculæ which were visible for several days previous and subsequent to the eclipse; and he has come to some remarkable conclusions, which render it very probable that the red prominences are identical with them, and not with the spots.

Theoretical Astronomy: Supplement

Thus, though we cannot say that very much has been done in establishing a satisfactory theory respecting the constitution of the various layers forming the solar atmosphere, yet every possible advantage has been taken of all the circumstances by which, during the last few years, additional knowledge could be gained. Several circumstances which were matters of speculation have become now well-ascertained matters of fact, and materials are laid up which may at some time not far distant tend to the formation of a satisfactory theory based on observation.

It has been tolerably well confirmed by recent observations, and especially by photographical representations of the sun, that the light at the centre is considerably more intense than that near the borders of the disk; and Professor Secchi has recently been engaged in a series of experiments, which seem to prove very distinctly that the same is true with regard to *heat*.

Secchi's experiments were made with a thermo-electric pile belonging to a Melloni's apparatus, attached to the telescope of the equatorial of the Collegio Romano at Rome, and some of his conclusions are very satisfactory. Amongst these, the most important conclusion is, that the heat of the solar image is at the centre almost twice as great as at the borders, whether estimated in the direction of right ascension or of polar distance. A second conclusion satisfactorily arrived at is, that the point of greatest heat was not exactly at the centre of the disk, but about 3′ above it in declination; and on constructing the curve of intensity, and considering the position of the sun's equator at the different times at which the experiments were made, the maximum line of heat appears to be coincident with the equator. Professor Secchi also thinks it not improbable that the two solar hemispheres possess different temperatures, as seems to be the case with the earth; and if so, he considers that his researches, if continued, will throw some light on the climatology of our planet; since the heat of the sun would be different, accordingly as one or the other of its poles is turned towards the earth. He also had occasion to remark, that the influence of solar spots upon the temperature was very striking; so that sometimes a spot which did not occupy more than one-hundredth part of the aperture of the pile, caused the temperature to fall 3°, or about one-fifteenth of the whole intensity.

CHAP. II.

OF THE MOON.

SECTION I.—*Correction of the Elements of the Lunar Orbit.*

The greatest work of the present century, tending to bring to perfection the theory of the motions of the moon, is the reduction, under the direction of Mr Airy, of the ancient lunar observations made at Greenwich. These observations extend from the time of Bradley to that of Pond, and embrace a period of eighty years, during which the nodes of the orbit in which the cycle of many of the perturbations is completed have made more than four revolutions. The number of observations made in this interval, and thoroughly discussed, amount to about 9000.

It has been fortunate also to the science of astronomy, that the same great astronomer who had courage to undertake the vast amount of labour connected with the reductions, has found leisure to deduce from the results the corrections of the elements of the orbit. The paper containing the investigation connected with the corrections of the elements, is printed in vol. xvii. of the *Memoirs of the Royal Astronomical Society*, from which we extract the following curious and important results.

Correction of the Epoch of Mean Longitude.

The correction of this element proved to be of very great service to the lunar theory, by eliciting from Professor Hansen the discovery of a new inequality, depending upon the action of Venus.

By dividing the observations into groups of about five years,

Theoretical Astronomy: Supplement

it was found that the corrections to Damoiseau's epoch of longitude were neither constant, implying that the mean motion was correct, nor uniformly increasing or diminishing, but that a periodic inequality was very clearly exhibited, showing the result of some unknown cause of disturbance. On the results being shown in MS. to M. Hansen, he very quickly traced the origin of the perturbation, and proved it to be due to the unequal action of Venus at different distances from the earth and moon. On the application of these inequalities for the respective epochs, the periodical inequality disappeared, and the successive corrections to the epochs of longitude for the different epochs showed an evident error of assumed mean motion, the secular correction to which was found to be + 39″·3.

Another important result deduced by Mr Airy, was the correction of Burckhardt's value of the moon's parallax, which he found ought to be increased by $\frac{1}{180}$th part.

Subsequently, however, Mr Adams (the English discoverer of the planet Neptune) has entered into a minute examination of Burckhardt's tables, especially with regard to the parallax; and has found errors of such a magnitude as to enforce the necessity of applying the requisite corrections to all the observed places of the moon in which this tabular parallax has been applied, including all for which the data of the Nautical Almanac have been employed in the reductions. Mr Adams's paper on the lunar parallax is added to the volume of the Nautical Almanac for 1856, and the requisite tables are given for deducing the corrections to be applied to the observed places of the moon which have been reduced with the erroneous parallax.

In Mr Airy's corrections of the elements of the lunar orbit, there is an inequality in the latitude of the form + 2″·17 × cos. moon's true longitude, which had not been detected by theory, but which clearly resulted from the observations. Professor Hansen, soon after the publication of Mr Airy's results, showed this also to be a legitimate deduction from theory, his calculated coefficient of the inequality being + 1″·38. The cause of the inequality he found to be due essentially to the circumstance, indicated by Laplace, of the invariability of the mean inclination of the orbit of the moon to the plane of the earth's orbit, as affected by the action of the planets. The development of the expression for the latitude, according to this law of the inclination, with a slight modification, was found to contain a term of the form required. The same train of investigation has given a new term in the expression for the moon's longitude = − 0″·50 × cos. long. of node, while that deduced from observation and hitherto unexplained = − 0″·97 cos. long. of node.

Again, in a subsequent communication to Mr Airy, M. Hansen announced that he had verified by theory another small term discovered by observation. According to his statement, he found the correction to Damoiseau's secular motion of the node to be + 1″·643, while Mr Airy's investigations had given + 1″·721.

SECTION II.—*Of Selenography, or Observations and Delineations of the Surface and Physical Peculiarities of the Moon.*

The surface of the moon has received that attention which might be looked for from the vast increase of optical power which has been recently brought into action, and from the zeal and talent which have been displayed in every department of physical research.

The most important delineation of the whole surface of the moon, as derived from observation, is that contained in the admirably executed map, accompanying the elaborate work by Beer and Mädler, entitled *Der Mond*. This map is the result of some years' careful study and micrometrical measurement of the surface of the moon, and every point discovered by the telescope is laid down with all attainable precision.

A raised model of the whole surface, deserving especial notice, was executed by Madame Witte, a Hanoverian lady, and exhibited in England in 1845. It is composed of a mixture of mastic and wax, forming a globe of about 12 inches in diameter, on which the positions and general outlines of the craters and other remarkable features were, in the first instance, laid down from their latitudes and longitudes, as given by Beer and Mädler, and the modelling was afterwards performed by the aid of a magnifying-glass from the actual appearance of the objects as presented in the telescope. Another original model, executed by the same lady, is laid up in the Royal Museum of Berlin.

Theoretical Astronomy: Supplement

Of English observers of the lunar surface, the most successful has been Mr James Nasmyth, a gentleman well known to the general, as well as the scientific public by his mechanical inventions. In the year 1844 he exhibited, and subsequently presented to the Royal Astronomical Society, a model and drawing of a portion of the surface, occupying a space of about 190 by 160 miles, the result of four years' careful and continuous labour. The observations were made with two reflecting telescopes, one of $8\frac{3}{4}$ inches aperture and 9 feet focal length, and the other of 12 inches aperture, and 13 feet focal length.

Mr Nasmyth has continued up to the present time to direct his attention to the lunar surface, and in the memorable year 1851 he exhibited, at the Crystal Palace in Hyde Park, some excellent models and charts of various portions of it. He has recently announced that he is still engaged in sketching and modelling the surface, employing for the purpose an excellent reflecting telescope of 20 inches aperture, with a power of 410. For Mr Nasmyth's ingenious speculations on the formation of the moon's craters, and on the apparent identity of the volcanic action with that existing on the surface of our own planet, the reader may consult the *Memoirs* and *Notices of the Royal Astronomical Society*.

Professor Secchi, to whom we are indebted for some valuable contributions to our knowledge of the heating properties of the solar surface, has also, in connection with Professor Ponzi, a distinguished Italian geologist, devoted considerable attention to the study of the surface of the moon, and furnished some remarkable speculations respecting the successive periods of volcanic action. We have not space for any detailed account of these speculations, for which the reader is referred to vol. xiii. of the *Notices of the Royal Astronomical Society*.

CHAP. III.

OF THE PLANETS.

Mercury.

The theory of the motion of Mercury has recently been most thoroughly investigated, and new tables have been constructed by M. Leverrier.

The investigation of the corrected orbit, which is contained in the additions to the *Connaissance des Temps* for 1848, is one of the most profound and laborious, and at the same time original, contributions to planetary astronomy, which have appeared during the last few years, and will well repay the perusal, both of the student and the accomplished astronomer.

We have space only for a brief explanation of the processes employed, and for a recapitulation of the principal results.

His object was to obtain new elliptic elements of the orbit from the Paris Observations made between 1801 and 1828, and between 1836 and 1842, and also totally to revise the whole theory of the perturbations of the planets, using the best modern elements, and taking in every term in the developments of the perturbing function which could possibly exercise the smallest influence on the place of the planet.

Using Lindenau's elements as the basis of his investigations, he first proceeds to prepare the expressions for the equation of the centre and the radius-vector, to the ninth power of the eccentricity. The next and most laborious part of the work is the original redetermination of the perturbations of the elements of the orbit. This process is described most elaborately, and the action of each of the planets is given. Assuming the provisional values for the masses of the disturbing planets, he gives the numerical values of the secular variations of the eccentricity, perihelion, inclination, and node of the orbit, and points out a serious error committed by Laplace in the determination of the secular variation of the equation of the centre. Lastly, after having in a most elaborate way calculated the periodical variations of the elements of the orbit, and of the heliocentric co-ordinates produced by each planet separately, he sums up the provisional expressions of the elliptic elements, and the perturbations, with every detail.

The next part of the work is the reduction of the observa-

Theoretical Astronomy: Supplement

tions, and the comparison of the observed and tabular places. For the reduction of the observations of R.A., his fundamental stars are taken from the *Tabulæ Regiomontanæ*: the right ascensions of the sun are taken from the *Connaissance des Temps*, but are corrected by the *Paris Observations*; the radii-vectores of the Earth's orbit are taken from Bessel's tables; and Bessel's obliquity of the ecliptic is adopted in the reduction to geocentric longitude and latitude. In the reduction of the observations of declination, the planet is compared with stars lying nearly in the same parallel, and observed by the same observer—the zenith point apparently not having been determined independently. The mean parallax of the sun is assumed to be 8″·6.

The observed right ascensions and declinations are then reduced to geocentric longitudes and latitudes; and the tabular heliocentric places are reduced by appropriate formulæ to geocentric longitudes and latitudes; and these, when corrected for aberration, are immediately comparable with the observed geocentric longitudes and latitudes, and the errors of the tabular places are thus found. These errors are then converted into errors of heliocentric longitudes and latitudes by the use of formulæ similar to those given in the *Introductions to the Greenwich Observations*, and involve the error of radius-vector. But the errors of longitude can be immediately expressed in terms of the errors of the epoch, mean motion, eccentricity, and perihelion, by differentiation of the expression for the true longitude, in terms of the mean anomaly and eccentricity; and the errors of latitude can be easily expressed in terms of the errors of inclination and node of the orbit; hence the two sets of equations are formed for the determination of the six elements of the orbit.

The next part of M. Leverrier's process is the collection and discussion of all the observations which had been made of the transits of the planet across the sun's disk, since those alone are capable of giving the exact position of the planet for more remote epochs.

Finally, he solves the equations resulting from the *Paris Observations* by the method of least squares, and obtains the errors of the elements.

One of the most important results is the correction which he finds it necessary to apply to the annual mean motion, namely, +0″·424. "The correction," he observes, "is large; but it is quite impossible without it to represent the ancient and modern observations completely."

M. Leverrier, for the purpose of testing the accuracy of his elements, applies them to the recomputation of the transits across the disk of the sun from the year 1661 to 1832; and the tabulated errors arising from the use of these elements, and those of Lindenau, being placed in adjacent columns, leave no doubt of the superior accuracy of the former.

He finally constructs two distinct sets of tables of the motion of the planets; one according to the old form, and the other according to a form totally original, and of which the chief peculiarity consists in taking the time for the sole argument throughout. The latter he considers to possess very great advantages, and enters into a minute critical investigation of the defects of all planetary tables constructed in the ordinary way.

Venus.

The planet Venus being so close a neighbour to the Earth and her satellite the Moon, it might be expected that she would produce serious disturbances on the orbits of these bodies. It has been seen that this is the case with regard to the Moon; and long before the discovery of this inequality, a very important inequality, of very long period, in the orbits of the Earth and Venus, produced by their mutual action, was detected by Mr Airy.

This investigation (one of the most laborious and remarkable in physical astronomy since the time of Laplace) is contained in Part i. of the volume of the *Philosophical Transactions* for 1832; and we will give a few of the leading features of the investigation, without any explanation of the abstruser parts of the discussion.

In Mr Airy's paper in the *Philosophical Transactions* for 1828, "On the Correction of the Elements of Delambre's Solar Tables," he had stated that the comparison of the corrections in the epochs of the sun, and the place of the perigee given by late observations, with the corrections given by the observations of the last century, appeared to indicate the existence of some inequality not included in the arguments of those tables; and as soon as he had convinced himself of the necessity of seeking for some inequality of long period, he commenced an examination of the mean motions of the planets, with the view of finding one whose ratio to the mean motion of the earth could be expressed very nearly by a proportion whose terms were small.

Theoretical Astronomy: Supplement

Venus is precisely in this predicament with regard to the Earth, since eight times the mean motion of Venus is so nearly equal to thirteen times the mean motion of the Earth, that the difference does not exceed $\frac{1}{272}$th part of the Earth's mean motion. This would imply an inequality whose period is about 240 years—a longer period with regard to the periodic time of the planets disturbed, than any for which a term of perturbation had been calculated.

The coefficient of the term of the expansion of the disturbing function in which this inequality exists, is of the fifth order with regard to the eccentricities and inclinations, and therefore would be exceedingly small; but on the other hand it would be multiplied in integration by a quantity amounting to $3 \times 13 \times (240)^2$ or about 2,200,000, and on this circumstance depended the chance of its becoming sensible.

The orbit of Venus has also received considerable attention during the present century, and the whole series of the Greenwich observations from 1750 to 1840 have been made available, and been employed to obtain the corrections of Lindenau's elements. These investigations, conducted successively by Mr Main, Mr Glaisher, and Mr H. Breen, of the Greenwich Observatory, will be found in various volumes of the *Memoirs of the Royal Astronomical Society*, to which the reader is referred, in connexion with the *Introductions to the Greenwich Observations*, for explanation of the peculiarities of the methods employed.

Mars.

The orbit of Mars has received at the hands of Mr H. Breen a revision similar to that bestowed on the orbit of Venus, by a comparison of the places computed from Lindenau's tables, with the Greenwich observed places from 1750 to 1830. The investigation is precisely similar to that for the orbit of Venus, and will be found in vol. xix. of the *Memoirs of the Royal Astronomical Society*.

Next to the transits of Venus across the sun's disk (which afford absolutely the best means of determining the solar parallax), the observations of Mars at his opposition are the most useful for determining this element. The observatory at the Cape of Good Hope is admirably situated relatively to Greenwich for such determinations, and, ever since the time of Lalande, comparisons of observations between the two observatories have been of great service to astronomy. Notwithstanding the apparently definitive value of the sun's parallax obtained from the transits of Venus in 1761 and 1769, astronomers have been so impressed with the importance of establishing the correctness of this element by all other available means, that, at every opposition of Mars, the places of stars suitable for comparison with the planet are published in the *Nautical Almanac*, and observed at Greenwich and the Cape, and at other places. At the opposition of 1851, a good series of comparative observations of the planet was made at the two observatories, and, as soon as the transit circle now in preparation is established at the Cape, we may hope for some comparative results which will be of still greater service for the determination of the parallax.

The shape of the planet has been well measured, and it appears certain that it has a measurable ellipticity, though there is still some doubt as to its amount. A good set of measures made at Greenwich with a double-image micrometer in 1845, gives $\frac{1}{152}$d for the ellipticity, and another set made in 1852, gives $\frac{1}{190}$th. M. Arago contends for a much larger ellipticity, namely $\frac{1}{103}$th, as the result of the Paris measures, and some observers have not been able, after careful measures, to detect any certain difference between the polar and equatorial diameters.

The physical peculiarities of the planet have been well studied. On this head the reader may consult various papers in the

Nachrichten, and especially one by Mädler in the sixteenth volume. Mr De la Rue devoted a portion of his leisure to the study of the surface of the planet at its last opposition, and has presented to the Royal Astronomical Society some admirably executed drawings of its appearance at various times.

The Small Planets whose orbits lie between Mars and Jupiter.

In no department of astronomy has more activity been displayed than in the discovery of these minute bodies; and the research necessary for discovering them acts very advantageously on the progress of the science, in the formation of charts of small stars lying near the ecliptic, or in regions of the heavens where they are likely to exist. Mr Bishop, at whose observatory in the Regent's Park so many of these bodies have been discovered by Mr Hind, has already published several ecliptic charts, containing all stars as low as the tenth magnitude inclusive, within a zone of 3° on each side of the ecliptic; and Mr Cooper of Markree in Ireland, at whose observatory Metis was discovered, has published in two volumes of observations, catalogues of 30,097 stars. Mr Cooper's telescope, mounted equatorially, has 25 feet focal length, with 14 inches aperture, and he is therefore possessed of peculiar advantages for these researches, and he is still more fortunate in securing the services of his active and talented observer, Mr Graham, the actual discoverer of Metis.

The first planet, Astræa, of the more modern group, was discovered, after an interval of several years, at the end of 1845, by M. Hencke of Driessen; and the next in order of discovery, Hebe, was also discovered by him in 1847. Since that time discoveries of other planets, by Hind, De Gasparis, and others, have followed in rapid succession, till at the present time we are acquainted with twenty-six of these bodies. We subjoin a table exhibiting the whole list, with the names of the discoverers, the dates of discovery, and relative magnitudes of their orbits subjoined. It is only necessary to explain, that they are placed in the order of their mean distances from the sun, as given by the orbits (many of them only provisional) which have been computed.

Name of Planet.	No. in Order of Discovery.	Discoverer.	Date of Discovery.	Mean Distance.	Sidereal Period in Days.

The discovery of so many of these small planets has made it necessary to seek for some more convenient method of computing their perturbations than that of mechanical quadratures formerly in use. The difficulty of the calculations consists in the largeness both of the excentricities and inclinations of the orbits, since it is by powers of these quantities or functions of them, that the effects of perturbation are expressed in the ordinary methods.

In a paper published by Professor Hansen in 1843, in the *Transactions of the Royal Academy at Berlin*, and since translated into the French language by Mauvais, and published in the *Connaissance des Temps* for 1847, a method is given by which the variations of these elements can be expressed in general terms by means of series converging with a sufficient degree of rapidity.

Professor Encke has for several years devoted considerable attention to the same subject, and has recently devised a method of remarkable simplicity for effecting the summations of the perturbations. The pamphlet containing the exposition and application of the method has been translated from the German by Mr Airy, with additional notes and illustrations, and is appended to the *Nautical Almanac* for 1856.

A remarkable paper by Mr G. P. Bond, on the same subject, is printed in the fourth volume of the *Memoirs of the American Academy*, entitled, "On some applications of the method of mechanical quadratures."

Jupiter.

On account of the vast size of the planet Jupiter, the determination of his mass is a matter of very great importance, and on account of the brightness of his satellites, this determination is easily effected by means of their observed elongations.

Till the year 1832, however, no observations of the satellites were extant which were sufficiently accurate for the purpose. At this time, Professor Airy made an excellent series of observations of the extreme elongations of the fourth satellite, and obtains for the value of the mass $\frac{1}{1047.7}$. In the years 1833 and 1834 he repeated the observations, and found for the mass the values $\frac{1}{1047.88}$ and $\frac{1}{1047.81}$. He finally caused a similar set of observations to be made with the Shuckburgh equatorial at Greenwich, in 1836, and found for the value, $\frac{1}{1047.92}$. The weights which he assigns to these results are 2, 2·3, and 8, and his definitive value is $\frac{1}{1047.77}$. The separate investigations will be found in vols. vi., viii., ix., and x. of the *Memoirs of the Royal Astronomical Society*.

About the time of the commencement of Mr Airy's observations, Bessel had undertaken the same problem on a more extended plan, including not only the determination of the mass of Jupiter, but a complete revision of the elements of the orbits of the satellites, by means of observations of their elongations. For this purpose he commenced with the Königsberg heliometer a very elaborate series of measures of distance and angle of position of all the satellites relatively to their primary, which was continued from 1832 to 1835, and then again taken up and completed in 1839. His resulting values of the mass are as follow:—

From the observations of the 1st satellite, ... 1048·381
... 2d ... . 1048·153
... 3d ... . 1048·143
... 4th ... . 1047·746

and from these values he deduces for the definitive value of the mass of the Jovial system $\frac{1}{1047.879}$.

Bessel's dissertation on the mass of Jupiter is contained in the second volume of the *Astronomische Untersuchungen*, a work containing several of the most profound researches of this eminent astronomer, published in 1842. The dissertation is accompanied by new tables of the satellites.

An investigation of the value of the mass of Jupiter was also made by Professor Santini at Padua in 1835, by observations of distance of the fourth satellite from the centre of the primary, made with a double-image micrometer furnished by Amici. The definitive result for the mass is $\frac{1}{1047.97}$, and this dissertation also is accompanied by tables of the motion of the fourth satellite. (*Memorie della Societa Italiana delle Scienze*, vol. xxi.)

With regard to the form of the planet Jupiter, the received value of the ellipticity for many years was that deduced by Struve at Dorpat—viz., $\frac{1}{14.7}$. (See *Memoirs of the Royal Astronomical Society*, vol. iii.) This value has, however, been found to be sensibly erroneous, by means of measures taken in several successive years at the Greenwich Observatory, with a double-image micrometer applied to the Sheepshanks equatorial. The value of the ellipticity, deduced from nearly fifty sets of measures averaging ten measures in each set, is $\frac{1}{14.7}$.

We may finally mention a valuable paper by Mr Woolhouse, on the satellites of Jupiter, which will be found in the appendix to the *Nautical Almanac* for 1835. It contains new tables for the calculation of the occultations of the satel-

lites, and of the transits of the satellites and shadows across the disk of the planet.

Saturn.

The additions made to our knowledge of the theory and physical constitution of this important member of the solar system have been very great. In treating of them, we will take in order the orbit, the uranography of the body, the form of the body, the rings, and [illegible] satellites.

The tables representing the motion of Saturn, which have been used to the present time, are those of Bouvard, and in the construction of them a curious error has been detected by Mr Adams, in his course of investigations concerning the orbit.

Mr Adams detected a periodical error of latitude of considerable amount, which, he felt convinced, could not arise from any imperfection in the theory of the perturbations; and on examining the law of the error, of which the period appeared to be nearly twice that of Saturn in his orbit, he traced it to Table xlii. in Bouvard's *Tables*. The formula given in the introduction is correct, but the computation of the whole table is totally erroneous.

Mr Adams gives, in the 14th number of vol. vii. of the *Notices of the Royal Astronomical Society*, a correct table of the values of the inequality in question, to which we would direct the attention of the reader.

In considering the various phenomena which must be constantly occurring before the eyes of a spectator situated on the surface of Saturn, attention is naturally directed to the effects which would be produced by the projection of the rings on the firmament of the spectator, and to the consequences resulting from its interposition for a long period between him and the sun. It has been generally considered, without entering into calculation, that, to the inhabitants below a certain latitude on the planet, the rings, stretching in a circular shape across the heavens, would present a magnificent spectacle for a certain number of years, or as long as the sun should continue on the same side of the ring with the spectator; but that an equally long eclipse, with total absence of light, would be suffered by the inhabitants after the passage of the sun to the other side of the ring.

Dr Lardner has recently shown, in an elaborate paper printed in vol. xxii. of the *Memoirs of the Royal Astronomical Society*, that this view of the subject is to a great extent erroneous; and that even Mädler, who, in his *Populare Astronomie*, has entered more minutely into the consideration of the uranography of Saturn, has made some grave errors in treating the subject. For the details of the investigation by Dr Lardner, we must refer to his paper.

The form of the planet Saturn has been the subject of considerable discussion at various times, but its strictly elliptical figure has been recently established beyond controversy, and the amount of the ellipticity has been very accurately determined.

At the time of the disappearance of the ring in the years 1832 and 1833, Bessel took the opportunity of measuring the planet with the heliometer, with the express view of deciding upon the correctness of Sir William Herschel's opinion, "that at middle latitudes the figure of Saturn deviated considerably from an ellipse," and also of determining accurately the amount of the ellipticity. He measured, therefore, in the directions of the polar and equatorial diameters, and of diameters lying nearly in latitude 45°, and found that the shape was strictly elliptical, and that the ellipticity, deduced from all the measures taken when the ring was either very small or totally invisible, was $\frac{1}{9.7}$th.

Recently, at the last disappearance of the ring in 1848, a series of measures was made with a similar object at Greenwich, by the Rev. R. Main, which give results almost identical with those of Bessel. The shape is proved, by a careful discussion of all the measures, to be strictly elliptical, and the deduced ellipticity is $\frac{1}{9.7}$. Mr Main's paper is printed in vol. xix. of the *Memoirs of the Royal Astronomical Society*.

With regard to the present physical condition of the surface of Saturn as well as of Jupiter, Mr Nasmyth has thrown out some ingenious conjectures based on the knowledge which the rapid advance of geological science has gained for us with regard to the former conditions of the surface of our own planet. Such inquiries are fair subjects of speculation in the present state of the physical sciences, and Mr Nasmyth's paper in No. 2 of vol. xiii. of the *Notices of the Royal Astronomical Society* is well worth perusal.

Amongst the most remarkable discoveries of recent times with regard to the *rings* of Saturn, is that of the *inner dusky or semi-transparent ring*, sufficiently obvious to any observer capable of using well a moderately good telescope, but which, previously to the year 1850, was scarcely suggested by any astronomer. It appears, however, by a paper by Dr Galle of Berlin, published in the *Nachrichten*, No. 756, and discussed with his usual judgment by Mr Dawes in the *Monthly Notices of the Royal Astronomical Society*, vol. xi. p. 184, that this interesting phenomenon was seen by him with the large Berlin refractor in the year 1838, though the observations were not published at the time in the *Nachrichten*, and the attention of the scientific world was not generally drawn to it. The account of Galle's observations, accompanied by drawings exhibiting the trace of the dusky ring as it crosses the body of the planet, was given by Encke in the *Transactions of the Berlin Academy* for 1838.

This was the only intimation of the existence of the inner ring received by the scientific world from that time till the year 1850, when its existence was recognized almost simultaneously by two observers, namely, by Professor Bond of the Cambridge Observatory, U.S., and by the Rev. W. R. Dawes at Wateringbury, near Maidstone. Since that time there has been no difficulty in seeing this curious appendage to Saturn, though it still requires a practised eye and a good telescope.

At the time of the discovery of the dusky ring, Mr Dawes also satisfactorily established the fact of the outer division of the exterior ring near its outer extremity; and subsequently he observed a series of discontinuous gradations of colour or intensity of brightness in a portion of the inner bright ring. He observes, that "the exterior portion of the inner bright ring to about one-fourth of its whole breadth was very bright, but that interior to this, the shading-off did not appear, as under ordinary circumstances, to become deeper towards the inner edge without any distinct or sudden gradations of shade; on the contrary, it was clearly seen to be arranged in a series of narrow concentric bands, each of which was darker than the next exterior one. Four such were distinctly made out; they looked like steps leading down to the black chasm between the ring and the ball. The impression I received was, that they were *separate rings*, but too close together for the divisions to be seen in black lines." This curious phenomenon was confirmed afterwards by Professor Bond.

Many valuable observations of Saturn and his rings have been made recently by Mr Lassell, who, in the autumn of 1852, established himself with his 20-foot reflecting telescope at Malta, for the purpose of observing in a purer atmosphere. Amongst his discoveries may be mentioned the fact of the *semi-transparency* of the dusky ring, which curious fact had been previously recognized by Captain Jacobs at the Madras Observatory.

Mr De la Rue has also devoted considerable attention to the system of Saturn, and has recently published an admirably executed drawing, which embodies the results of his observations.

We would, before concluding our remarks on the rings of Saturn, draw attention to a remarkable paper by M. Otto Struve, printed in vol. v. of the *Petersburg Memoirs*. M. Struve shows with tolerable certainty that the inner or dusky ring is not a modern appendage to the planet, as might almost be suggested by the fact of its remaining so long undiscovered; but that at the beginning of the eighteenth century, the dark line thrown by it across the planet was not confounded with the shadow of the bright rings, but was known by the name of the *equatorial belt*.

But one of the most curious results of M. Struve's researches is, that by a comparison of the micrometrical measures of Huyghens, Cassini, Bradley, Herschel, W. Struve, Encke, Galle, and himself, he finds that the *inner edge of the interior bright ring is gradually approaching the body of the planet, while at the same time the total breadth of the two bright rings is constantly increasing*.

An *eighth* satellite of Saturn was discovered in 1848, independently, and almost simultaneously by two observers, Professor Bond and Mr Lassell. The names of the seven satel-

lites previously known, proposed by Sir J. Herschel, were Mimas, Enceladus, Tethys, Dione, Rhea, Titan, and Iapetus. For the new satellite Mr Lassell proposed the name Hyperion. Its period, as determined by Mr Lassell, from a comparison of observations made in 1850 with those made in 1852 and 1853, is 21·297 days; and, in order of distance from Saturn, it lies between Titan and Iapetus, the latter being the exterior of all.

Uranus.

For many years the orbit of Uranus has been the occasion of great embarrassment to astronomers, from the impossibility of adequately reconciling the ancient and modern observations by any one set of elements, and from the rapid increase of the tables from year to year.

Amongst the astronomers who entered seriously upon the task of tracing the course of the irregularities in the motions of the planet we can only mention those who arrived at a successful solution of the problem; namely, M. Leverrier and Mr Adams, each of whom has attained to a world-wide celebrity by the profound and masterly analysis which led to the discovery of the disturbing planet Neptune.

In France the attention of M. Arago had been particularly directed to the subject; and about the year 1845 he earnestly represented to M. Leverrier the importance of the question, and induced him to lay aside the cometary researches on which he was engaged, and to enter upon the painful and laborious calculations which the problem demanded.

The first part of M. Leverrier's work consists of a complete revision of the theory of the perturbations of Uranus; and his first memoir, which was presented to the Institute in November 1845, is devoted to the exact redetermination of the perturbations produced by Jupiter and Saturn; and this profound investigation is conducted with the same masterly skill which distinguished his researches on the orbit of Mercury.

The second memoir was read before the academy on June 1. 1846, and has for its chief object the comparison of the observed places of Uranus with the tabular places computed by Bouvard's tables, corrected according to the previous investigations for the new inequalities produced by Jupiter and Saturn, and for such other errors as had been discovered in the progress of the work. He arrives at the important conclusion, that though large errors existed in the tables, and through this cause alone they could not correctly represent the observations, yet that the difference existing between theory and observation could not be adequately accounted for by such imperfections, and that the cause of the "discordances" must be sought for elsewhere.

It is but just to Mr Adams to state, that he also, before entering upon the task of accounting for the discrepancies observed, by the hypothesis of an exterior disturbing planet, recomputed all the principal inequalities produced by the action of Jupiter and Saturn, and satisfied himself that errors in the tables would not account for the failure in the agreement between theory and observation.

With regard to the satellites of Uranus some considerable discoveries have been made, though modern research has failed to identify the greater number of those seen by Sir W. Herschel. However, two additional satellites *certainly* (and probably three) were found in 1847 by the exertions of Mr Lassell and M. Otto Struve, each of which is nearer to the planet than any of those discovered by Sir W. Herschel. In the *Notice of the Royal Astronomical Society* for January 1848, will be found the account given by each of these astronomers of the discovery of at least one satellite interior to the second of Sir W. Herschel. Mr Lassell observed the same object for several nights, and on one occasion he observed an additional one, the positions of the object observed being always on the north side of the planet. M. Otto Struve, on the contrary, observed an object always on the south side only of the planet. In the *Notice* for March 1848, will be found a paper by Mr Dawes, in which he discusses very thoroughly the whole of the observations made by both astronomers, and arrives at the conclusion that the objects observed by them are not identical, and consequently that *two* satellites must have been discovered.

Mr Lassell has since that time been able to follow up the observations of both these bodies, and by a comparison of the observations made by him in 1847, 1851, and 1852, he finds for the period of the inner satellite which he calls Ariel, 2·520378 days, and for the period of the exterior one (Umbriel) he deduces 4·144557 days.

By a rigorous scrutiny of all the observations made by the two Herschels, Dr Lamont, and Mr Lassell, of the two bright satellites of Sir W. Herschel, Mr Adams finds for their periods $8^d\ 16^h\ 56^m\ 24^s{\cdot}88$, and $13^d\ 11^h\ 6^m\ 55^s{\cdot}21$.

Neptune.

In whatever light we regard the discovery of the planet Neptune, it must certainly rank amongst the most brilliant of the discoveries of the present century;—the highest achievement in an age abounding with every resource of science and intellectual cultivation.

It has been stated that Leverrier undertook the task of the revision of the theory of Uranus at the instance of M. Arago, that his first memoir on the subject was read before the French Academy in November 1845, and that his second memoir was read in June 1846. These memoirs were printed in the *Comptes Rendus*, vols. xxi. and xxii. In the second memoir Leverrier demonstrates that an account of the motions of Uranus can only be given by the introduction of the disturbing force of a new exterior planet, and he fixes its position for 1847, January 1, at 325° heliocentric longitude.

The third memoir, entitled "*Sur la planète qui produit les anomalies observées dans le mouvement d'Uranus—Détermination de sa masse, de son orbite, et de sa position actuelle,*" was read on August 31. 1846. In it the position of the disturbing planet is fixed more exactly at 326° 32′ heliocentric longitude for 1847, January 1.

The three memoirs mentioned above were read before the discovery of the planet;—the fourth memoir, containing the remaining part of M. Leverrier's investigations, was read after its discovery, on October 5. 1846, and both this and the third are printed in vol. xxiii. of the *Comptes Rendus*. The fourth memoir is entitled "*Sur la planète qui produit les anomalies observées dans le mouvement d'Uranus; cinquième et dernière partie, relative à la détermination de sa position au plan de l'orbite.*"

Finally, the whole investigation was printed as one continuous treatise in the *Additions* to the *Connaissance des Temps* for 1849.

The discovery of the disturbing planet followed almost immediately after the publication of the third memoir of Leverrier. In acknowledging the receipt of a paper from his friend Dr Galle of Berlin, he took the opportunity of requesting him to search for the planet with the large refracting telescope of the Berlin observatory, at the position which he indicated to him. This letter reached Berlin on September 23, and on the same evening Galle had an opportunity of complying with the request contained in it. He observed all the stars in the neighbourhood of the place indicated, and compared their places with those given in Bremicker's Berlin Star-Map (Hora xxi.) This map, it is necessary to say, had not yet reached England, and on this circumstance probably depended the priority of discovery at Berlin. He very quickly found a star of about the eighth magnitude, nearly in the place pointed out, which did not exist in the map. Little doubt was entertained at the time that this was the planet, and the observations of the next two days confirmed the discovery.

It will now be necessary to explain in few words the attempts made in England during the same period of time to secure the discovery of the planet. Mr Adams had, ever since the year 1841, determined on attempting the solution of the problem relating to the unknown disturbances of Uranus, and in 1843 he began his investigations. In September 1845, he communicated to Professor Challis the values of the elements of the orbit of the supposed disturbing planet, and, in the following month, he communicated to the astronomer-royal the same results slightly corrected. Mr Airy entered into correspondence with him, and requested to be informed whether the assumed perturbations would explain the errors of radius-vector as well as of longitude. From some unexplained cause, no answer was received to this letter, and no steps were taken in England to secure by observation the discovery of the planet till the summer of 1846, after the publication of Leverrier's

Theoretical Astronomy: Supplement

second memoir, in which the same position, within one degree, was assigned to the disturbing planet, as that given in Mr Adams's paper.

The resources of the Cambridge Observatory were now brought into use for the discovery of the planet, and a systematic search was begun by Professor Challis with the great Northumberland telescope. With regard to the success of the system devised for conducting the observations, it is sufficient to say that the sweeps of the portion of the heavens in which it was supposed the planet would be found, were begun on July 29, and the planet was actually observed on August 4, but without recognition. After the discovery of the planet at Berlin, it was found that the planet had also been observed on August 12. If, therefore, Bremicker's map had been in the hands of Professor Challis, or if he had found leisure for the mapping of his observations from night to night, Neptune would have been infallibly detected within a very few days of the commencement of the search, and the whole glory of the discovery would have belonged to the English geometer.

The subsequent history of the planet may be summed up in few words. An ancient observation in Lalande's catalogue was discovered almost simultaneously by Mr Walker, of the Washington Observatory, and by Dr Petersen at Altona; two observations, the one in October 1845, and another in September 1846, were also detected by Mr Hind in Lamont's Zones; and these (especially the former) contributed greatly to the construction of an accurate orbit. An excellent orbit was computed by the joint labours of the American astronomers Peirce and Walker, which, up to the present time, continues to represent perfectly the motions of the planet.

Our sketch of the history of Neptune is necessarily so imperfect, through want of space for details, that we feel it necessary to add a list of the principal works to be consulted by those who are desirous of obtaining correct notions on all points relating to this brilliant discovery.—1. Airy's *Account of some circumstances historically connected with the Discovery of the Planet exterior to Uranus.—Notices of the Royal Astronomical Society*, vol. vii., p. 121; 2. Gould's *Report to the Smithsonian Institution on the History of the Discovery of Neptune*; 3. Lindenau's *Beitrag zur Geschichte der Neptun-Entdeckung*, in the *Erganzung-Heft* to the *Astro. Nachr.* published in 1849; 4. Sir J. Herschel's account in his *Outlines of Astronomy*.

Almost immediately after the discovery of Neptune, it was found to be attended by one satellite. This discovery was made by Mr Lassell in October 1846, and the orbit of the satellite is found to be inclined to the elliptic at an angle of about 35°. By observations of this satellite at Cambridge in America, and at Pulkowa, two separate values of the mass, namely, $\frac{1}{19710}$ and $\frac{1}{19380}$, have been deduced; but the object is so difficult to observe that a considerable time must elapse before any very accurate determination will be arrived at.

CHAP. IV.

OF COMETS.

On the chief Discoveries recently made in Cometary Astronomy.

The discoveries in Cometary Astronomy have kept pace with those in the other departments of the science.

With regard to theory, it has become of great importance, on account of the great number of comets which are discovered, to ease as much as possible the practical difficulties of the methods of computing the orbits, and many excellent papers will be found in the *Astronomische Nachrichten*, and in the *Memoirs of the Royal Astronomical Society*.

In particular, we would refer to a paper by Mr Airy, in vol. xi. of the *Memoirs*, the object of which is to render Laplace's method of computing the orbit of a comet easier of application, by enabling the computer to deduce the orbit immediately from the observed right ascensions and declinations, without the conversion of those quantities into longitudes and latitudes. This method evidently requires that the co-ordinates of the sun referred to the equator should also be computed; and these co-ordinates have therefore been given for some years past in the *Nautical Almanac*.

For an excellent method of calculating an ephemeris of a comet from its elements, we would also refer to a paper by Mr Woolhouse, in the appendix to the *Nautical Almanac* for 1835.

Theoretical Astronomy: Supplement

We will now proceed to give brief notices of some of the most remarkable comets which have appeared during the present century. For full information, and for complete catalogues of comets, the following works may be referred to:—1. Jahn's *Verzeichniss aller bis zum jahre* 1847 *berechneten Cometen-bahnen*, Leipzig, 1847; 2. Hind's work, entitled *The Comets*, London, 1852; 3. Cooper's *Cometic Orbits*, Dublin, 1852; 4. Encke's valuable edition of Olbers's *Abhandlung*, Berlin, 1847.

Encke's Comet, or *Comet of Pons*.—This comet was discovered in October 1805, almost simultaneously by Pons and other astronomers, being the third observed appearance. At this apparition it was sufficiently bright to be seen with the naked eye. Its next apparition was in 1818, when it was again discovered by Pons on November 26. By calculations according to Gauss's methods, based upon the great number of observations made at this apparition, Encke proved the orbit to be an ellipse, with a period of about $2\frac{3}{4}$ years, and established its identity with the comets which appeared in 1786, 1795, and 1805. To do this it was necessary to calculate the whole of the perturbations which it had experienced from the large planets, from the time of its apparition backwards to the dates of the other apparitions. This enormous labour Encke satisfactorily accomplished in a very short space of time; and the comet has ever since been called most commonly after his name. Since that time it has been observed at most of its apparitions, of which one of the most favourable for observation was in 1838. It was in the discussion of the elements of the orbit from the observations made at this apparition, compared with the previous ones, that Encke was induced to enter seriously upon the celebrated problem of the retardation probably experienced by the comet by a highly-attenuated resisting medium. The value of the *constant of resistance* was afterwards definitely determined by him, and the disturbance produced by this singular cause has been introduced into every subsequent discussion of the orbit.

In the year 1805 appeared the comet now known as *Biela's Comet*, also of short period. It was discovered by Pons on November 10. It was afterwards observed at the apparitions of 1826, 1832, and 1846, and at the last appearance presented the remarkable phenomenon of a double comet, both components being together in the field of the same telescope. Its period is rather less than seven years.

In 1807 appeared a *great comet*, surpassing in splendour any which had appeared since 1769. One of the most remarkable phenomena attending it was a double tail.

In 1811 appeared a *very splendid comet*, whose appearance is still remembered by many persons yet living. Its orbit was so situated that for many months it was circumpolar, and this added to the lustre of its appearance. In October the tail extended over an arc of 25° in length.

In 1812 appeared a *fine comet*, at one time visible to the naked eye. It was discovered by Pons on July 20. Encke calculated elements, giving a period of about 71 years.

In 1819 a *great comet* suddenly made its appearance at the beginning of July. The tail was about 7° in length, and at one time it must have transited the sun's disk.

In 1823 appeared a *comet* worthy of notice, from the fact of its exhibiting two tails, of which one was turned towards the sun, and the other in the opposite direction.

In 1825 appeared a *great comet*, which was discovered independently by Pons and Biela in July, and continued visible till the same season of the following year. The tail, which was double, extended over an arc of 15°.

In 1830 appeared *two comets*, visible to the naked eye, the first of which was discovered by Gambart in April. Each was attended by a tail, and the nucleus of each was bright.

In 1835 appeared, according to prediction, the famous *comet of Halley*. It was first detected at Rome by Dumouchal, on the 5th of August 1835, and was observed till May 1836; and excellent series of observations of it were made at the greater number of the observatories both of the northern and southern hemisphere. For particulars of its appearance, the reader

Theoretical Astronomy: Supplement

may consult Sir J. Herschel's *Results of Observations made at the Cape of Good Hope;* the *Memoirs of the Royal Astronomical Society;* and Struve's *Beobachtungen des Halley-schen Cometen*, where admirable drawings will be found of its appearance at various phases. To these may be added Bessel's drawings in the *Astronomische Nachrichten*, No. 302.

Westphalen's elliptic orbit corresponds to a period of about 76 years.

In 1843 appeared the most remarkable comet of the present century, familiarly known as the *great comet of* 1843. This comet came suddenly upon astronomers in all its brightness. the immense tail being first seen in England in the month of March, like a long band of light cirrous cloud, not very high above the south-west horizon soon after sunset.

For accounts of its physical appearance, we are indebted chiefly to accounts given by officers of ships on their passage to England from the southern seas, and a great number of such accounts will be found in vols. v. and vi. of the *Notices of the Royal Astronomical Society*. As seen by southern observers, the spectacle presented by it must have been very grand. The tail extended over an arc varying from 30° to 45°, and its breadth was so great that it produced the effect of two distinct streams of light united at the head of the comet, but separated throughout nearly the whole length by a dark interval.

But the most remarkable observations of this comet were made in America at the time of its nearest approach to the sun's disk, in broad daylight, by Mr J. G. Clarke, at Portland, in the State of Maine. He measured the distance of the nucleus from the sun (about 3½°) in strong sunshine, and states that it and the tail were as well defined as the moon in a clear day, and resembled a perfectly pure white cloud.

In 1843 was also discovered a *comet of short period*, by M. Faye, which has been the subject of some remarkable papers by Leverrier, in vols. xx., xxv., and xxvi. of the *Comptes Rendus*. The period of this comet is about 7½ years, and it was observed on its return in 1850.

In 1844 another *periodical comet* was discovered by De Vico at Rome. The period is about 1993 days, but it was not observed at its return in 1850, owing to its unfavourable position.

In 1845 a *bright comet* was discovered by Colla at Parma, on June 2. It was at one period visible to the naked eye, and exhibited a tail.

In 1846, on February 26, an interesting *periodical comet* was discovered by Brorsen. The period is about 5½ years. It was not seen at its return in 1851, being very near the sun at the time of its perihelion passage.

In 1847, a *remarkable comet* was discovered by Mr Hind on February 6. Before its perihelion passage, it became bright enough to be seen in the morning twilight, and it was observed close to the sun on March 30, at noonday.

In 1850, on May 1, a *comet* was discovered by Petersen, which became bright enough to be visible to the naked eye, with a tail several degrees in length.

In 1851, Brorsen discovered a *bright comet* on October 22, which exhibited a double tail.

In the present year 1853, a *comet* was discovered by Klinkerfues at Gottingen, on June 10, which in August became very bright, and for several evenings was a splendid object in the west, seen after the setting of the sun. It exhibited a tail perfectly straight, of several degrees in length.

CHAP. V.

OF THE FIXED STARS.

SECT. I.—*Star Catalogues.*

Within the last few years very many valuable *Star Catalogues* have been added to the list, through the combined labours of public and private observers. We can give only the names of a few of the most important, with such notices of their construction as seem necessary.

1. The Catalogues of Ptolemy, Ulugh Beigh, Tycho Brahé, Halley, and Hevelius, have been admirably edited by Mr Baily, and form vol. xiii. of the *Memoirs of the Royal Astronomical Society*.

2. Flamsteed's Catalogue in the *Historia Cœlestis* has been also edited by Mr Baily, and was published in 1835, together with his life of Flamsteed.

3. A Catalogue of the Stars in Lalande's *Histoire Céleste* (about 40,000 in number), edited and compiled by Mr Baily. at the expense of the British Association, and printed at the expense of the Government in 1847.

Theoretical Astronomy: Supplement

4. The Catalogue of Stars of the *British Association*, containing 8377 stars, edited by Mr Baily. 1845.

5. Lacaille's Catalogue of 9766 Stars, reduced at the expense of the British Association, under the superintendence of Professor Henderson, and printed at the expense of the Government, under the direction of Mr Baily, with Preface by Sir J. Herschel. 1847.

6. Sir Thomas Brisbane's Catalogue of 7385 Stars, chiefly in the Southern Hemisphere, observed at Paramatta. 1835.

7. Groombridge's Catalogue of Circumpolar Stars, edited by Mr Airy. 1838.

8. Johnson's Catalogue of 606 Principal Stars in the Southern Hemisphere. 1835.

9. Argelander's Catalogue of 560 Stars exhibiting Proper Motions observed at Abo. 1835.

10. The Greenwich Twelve-Year Catalogue of 2156 Stars. 1849.

11. Taylor's Madras Catalogue of 11,015 Stars. 1844.

12. Weisse's Catalogue of those Stars in Bessel's Zones, situated in a Zone extending 15° North and South of the Equator. 1846.

13. Oeltzen's Catalogue of the Stars in Argelander's Zones, situated between 45° and 80° North Declination. 2 vols. 1851 and 1852. (This valuable Catalogue forms vols. i. and ii. of the Third Series of the *Annalen des k. k. Sternwarte in Wien.*)

14. Rümker's Catalogue of 12,000 Stars. 1843–1851.

15. Cooper's two Catalogues of 30,097 Stars near the Ecliptic, observed at Markree. 1851 and 1853.

Several other Catalogues will be found in the *Memoirs of the Royal Astronomical Society*, but we have not space for separate accounts of them.

The following Catalogues of Double Stars must be mentioned:—

1. Struve's Great Catalogue of Double and Multiple Stars, observed at Dorpat. 1837.

2. Struve's Catalogue of 514 Double and Multiple Stars observed at Pulkowa. 1843.

3. Herschel and South's Catalogue of 380 Double and Triple Stars. (*Phil. Trans.* for 1825.)

4. Dawes's Catalogue of 121 Double Stars, observed at Ormskirk in the years 1831–1833. (*Memoirs of the Royal Astronomical Society*, vol. viii.)

5. Smyth's Cycle of Celestial Objects. 2 vols. 1844.

6. Struve's Catalogue of the Mean Places of the Stars observed at Dorpat from 1822 to 1843. 1852.

SECTION II.—*Of the Apparent Magnitudes, Number, and Distribution of the Stars.*

In any scheme for the re-arrangement of the stars in new constellations or *asterisms*, according to the views of Sir John Herschel (*Memoirs of the Royal Astronomical Society*, vol. xii.), or for thoroughly correcting the old arrangement of the constellations, a knowledge of their relative brightness or apparent magnitudes is absolutely necessary; yet this department of the science remains, even at present, in a very unsatisfactory state; and the estimated magnitudes set down in our best catalogues are always vague, and frequently inaccurate.

Notwithstanding this, however, several successful attempts have been made by eminent astronomers to put this branch of science on a better footing; and, under this head, its progress is mainly due to Argelander, Herschel, Johnson, and Dawes.

Argelander's remarkable work, the *Uranometria Nova*, published in 1843, gives for the northern heavens the most accurate scale of magnitudes for all stars visible to the naked eye, though the estimations do not profess greater accuracy than the descending scale of thirds of magnitudes employed by him will furnish.

Sir J. Herschel, while at the Cape, made the estimation of the magnitudes of the stars on a better system than any formerly employed—one of his most important subjects; and by naked-eye observations alone has assigned magnitudes to nearly 500 stars on a systematic plan, and with a degree of demon-

Theoretical Astronomy: Supplement

strable accuracy far exceeding anything which had been previously attempted. For a detail of his methods we must refer to his *Observations at the Cape of Good Hope.*

Mr Dawes has also been successful in devising a method for observing the magnitudes of telescopic stars, which is very easily applicable, and requires only ordinary perseverance and laborious observing, to establish, on a perfectly satisfactory basis, a scale of magnitudes for all telescopic stars in the heavens. (See *Monthly Notices of the Royal Astronomical Society*, vol. xii.)

Mr Johnson has also, in the course of his re-observation of the stars of Groombridge's Catalogue, paid great attention to the correct estimation of their magnitudes, and has lately devised a method, by the use of the heliometer, for comparing directly the magnitudes of such stars as lie within its range, so as to be brought into the same field. The results of his researches are published in a pamphlet appended to his last published volume of observations.

On the subject of the *number and distribution of the stars*, a most valuable work was published by the elder Struve in the year 1847, entitled *Etudes d'Astronomie Stellaire ; sur la Voie Lactée et sur le distance des Etoiles Fixés;* which gives a most lucid account of his own elaborate researches on this subject distributed throughout his other works, and especially of his preface to Weisse's Catalogue. Of this treatise an excellent abstract was given by Mr Airy, and is included in the *Report of the Council of the Royal Astronomical Society* of February 11, 1848, printed in the *Monthly Notices*. To this extract we must refer the reader for further information.

The almost-despaired-of problem of finding the *distances* of some of the fixed stars, has been successfully solved during the present half-century ; and in no branch of astronomy has the perfection, both of the theoretical and practical methods adopted by modern astronomers, been more severely tested, or more triumphantly successful.

The star 61 Cygni, a binary system of two stars of very nearly equal magnitudes, connected by gravity, and having a large proper motion, is that of which the parallax was first detected and measured by Bessel, by means of comparative measures of distance made with the heliometer, extending from the year 1837 to 1840, of which the whole series will be found in vols. xvi. and xvii. of the *Astr. Nachr.* The definitive value of the parallax arrived at is 0″·3483, which corresponds to a distance of about 600,000 radii of the earth's orbit.

Theoretical Astronomy: Supplement

The bright southern star α Centauri, has also had its parallax determined with great care by several series of meridian observations of zenith distance made by Professor Henderson and Mr Maclear. The resulting parallax amounts to very nearly 1″.

The parallax of α Lyræ was determined by micrometrical measurements, made by M. Struve, of its distance from a neighbouring faint star. The series of observations extended from November 1835 to August 1838, and the resulting value of the parallax is 0″·2619.

But the most remarkable paper on annual parallax is that by M. Peters of the Pulkowa Observatory. He gives in this paper the results of the meridian observations made with Ertal's circle, to determine the parallaxes of the stars Polaris, Capella, ι Ursæ Majoris, Groombridge 1830 (having large proper motion), Arcturus, α Lyræ, α Cygni, and 61 Cygni. The results he arrives at are as follow :—

	Parallax.	With prob. error.
For Polaris	+ 0″·067	0″·012
... Capella	+ 0·046	0·200
... ι Ursæ Majoris	+ 0·133	0·106
... Groombridge 1830	+ 0·226	0·141
... Arcturus	+ 0·127	0·073
... α Lyræ	+ 0·103	0·053
... α Cygni	− 0·082	0·043
... 61 Cygni	+ 0·349	0·080

We have endeavoured in the preceding pages to give a few of the most prominent of the researches and discoveries which have enriched astronomical science in the present century; but the very small space which could be allotted for this extension renders of necessity the accounts very imperfect, and forbids any details. It is hoped, however, that the references given will enable the reader to obtain for himself the full details of investigations of which we have only indicated the outlines, and to study fully the methods by which the results given in the preceding pages have been arrived at. (R. M—N.)

PART III.[1]

PHYSICAL ASTRONOMY.

The whole science of astronomy may be reduced to two general problems. The first is to express the position of all the heavenly bodies in terms of the time reckoned from a given instant, either in the past or the future duration of the world. The same may be otherwise stated by saying, that the thing required is, to express the position of any one of the heavenly bodies in a function of the time, the time being considered as the only variable quantity, though combined with other known quantities, which enter into the function as the co-efficients of the different terms. This is the most general view of that which is usually called descriptive, or sometimes geometrical astronomy. The solution of this problem enables us to determine for any time the places of the heavenly bodies, relatively to one another, and relatively to any point on the earth's surface. It contains under it an endless variety of subordinate problems, embracing a long series of successive generalizations, from the first observations to the determination of the orbits of the heavenly bodies, and the final reduction of all that concerns their motions into the form of astronomical tables. The second problem is, to compare the laws of motion in the heavens, as discovered from the preceding investigations, with the laws of motion as already known on the surface of the earth, in order to find out whether or not they are the same; and, if not, in what their difference consists. The solution of this problem constitutes what is called Physical Astronomy: it is the same with inquiring into the causes of the celestial motions; for by *causes* we mean the general facts concerning the motion of bodies which are observed to take place on the surface of the earth.

Though the first of these two problems goes necessarily before the second, for the solution of which it affords the *data*, yet, after this solution is obtained, it affords great assistance to many of the researches involved in the first, and exemplifies, in a most remarkable manner, the use of theory in the investigation of facts, and the re-action, as it were, of the second problem on the first.

Taking for granted the solution of the first problem, as given under the other Parts of this article, we are now to

[1] This portion of the present treatise is reprinted from the article on Physical Astronomy contributed by the late Professor Playfair to the *Supplement* to the fourth, fifth, and sixth editions of this work. The chief alteration made in this, the eighth edition, is the substitution of the differential for the exploded fluxional notation.

Physical Astronomy.

consider the second, and to explain the manner in which it has been resolved by Newton and the philosophers who have come after him.

The history of the first of these two problems is long and interesting, beginning from the remotest period to which the records or the traditions of mankind have ventured to ascend, and coming down to the present time; and, in the ages to come, it is never likely to know any limit but the movable instant which separates the past from the future,—as long, at least, as science and civilization are inhabitants of the earth.

The history of the second comes within small compass; because, between the first rude effort and the last refined investigation there is hardly any intermediate step but one.

The concentric orbs of the ancient philosophers were an attempt at an explanation of the physical causes of the celestial motions, or at an assimilation of those motions to such as we are accustomed to see on the surface of the earth. The great phenomenon to be explained was the diurnal motion of the heavens, by which so many bodies, very distant from one another, all describe circles round the earth, keeping time so precisely with one another, that the revolutions, whether great or small, are accomplished in the same interval. This could not be, unless a connection subsisted between those bodies; and the most simple idea of that connection was, that the bodies were fixed in the surface of a sphere which revolved on an axis, and carried them along with it.

If the whole of astronomy had been confined to the single fact of the diurnal revolution of the fixed stars, the hypothesis just mentioned would have been quite satisfactory. But as some of the heavenly bodies, such as the sun and planets, did not revolve precisely in the same time with the rest, it was necessary to assign to them particular spheres of their own. Those spheres, therefore, must be transparent: light must find an easy passage through them, and hence they must be crystalline. By degrees, as more accurate knowledge was obtained of the motion of the planets, it was found necessary so to increase the number of the spheres, that the complication of the structure was burdensome to the imagination; the hypothesis did not answer the very first object of a theory, that of connecting the facts together; and it was so unlike any process of nature with which we are acquainted, that it was highly improbable. The hypothesis of the homocentric orbs therefore fell into discredit, and, after the discovery of the earth's motion, was entirely abandoned.

The next attempt to explain the whole system of the celestial motions was that of Descartes, by means of vortices of subtile matter, and the pressure which, by the centrifugal force of those vortices, was produced on the grosser bodies of the stars. But as a taste for accurate knowledge increased, and as men reflected more on the true objects of philosophic theory, the system of vortices appeared more and more defective, and at length ceased to have any followers.

Newton succeeded, who, rejecting all the cumbersome machinery, both solid and fluid, of his predecessors, adopted a plan far more philosophical in the design, and far more difficult in the execution, than any thing yet known in the physical or mathematical sciences. Assuming as true the three general facts concerning the planetary system known by the name of the laws of Kepler, he proceeded to inquire by what sort of action on one another the planets could be made to describe orbits having the properties indicated by these three general facts. The general facts to which we now refer, are,

I. *That every planet moves so, that the line drawn from it to the sun describes about the sun areas proportional to the times.*

II. *That the planets describe ellipses, each of which has one of its foci in the same point, viz. the centre of the sun.* Physical Astronomy.

III. *That the squares of the times of the revolutions of the planets are as the cubes of their mean distances from the sun.*

Sect. I.—*Of the Forces which retain the Planets in their Orbits.*

1. *If a body gravitating to a fixed centre have a motion communicated to it in a direction not passing through that centre, it will move in a curve, and the straight line drawn from the body to the centre will describe areas proportional to the times.*

Let S (fig. 109) be the centre to which the body A gravitates, at the same time that a motion is communicated to it in the direction AB. And first, let the gravitating or centripetal force be supposed to act, not continually, but at intervals, producing instantaneously, at the beginning of each interval, the same velocity that it would have produced by acting continually during the whole of that time: let AC be the space which the body would describe by the action of this force alone; also let AB be the space which it would describe in the same time by the projectile force acting on it alone. It will therefore describe the line AD, the diagonal of the parallelogram contained by AB and AC, and at the end of the first interval will be in D. If, then, no new impulse of gravity were to act on it, it would in the second interval of time go on in the direction AD, and describe DF equal to AD. But if, at the beginning of the second interval, an impulse of the centripetal force be instantaneously impressed, sufficient to carry the body in that time from D to E in the line DS, it will describe the line DG, the diagonal of the parallelogram contained by DE and DF. The same is true of the third interval, in which the body will go from G to L, and of every subsequent interval. Join SB, SF, SK, &c. The areas of the triangles ABS, ADS are equal, the triangles being on the same base AS, and between the same parallels AS and BD. For the same reason, the triangles DGS, DFS are equal, and DFS is equal to ADS, because they have equal bases and the same altitude. For the same reason, the triangle SGL is equal to SDG, or to ADS; and the same is true of all the other triangles that are described in the equal intervals of time by the line drawn from the body to the centre S. This holds, however short the intervals may be, and however great their number; and therefore it is true when the intervals are indefinitely small, and their number infinitely great, that is, when the action of the centripetal force is continued. Plate LXXXIX.

But when the intervals of time become indefinitely small, the rectilineal figure ADGL passes into a curve. For when these intervals diminish, the lines AB, DF, &c. the lengths of the parallelograms, diminish in the same proportion; but the lines AC, DE, &c. the breadths, diminish in a greater proportion, viz. in that of the squares of these intervals. Hence, the angles which AD, DG, GL, the diagonals, make with the sides AB, DF, GK, continually diminish; and therefore the angles ADG, DGL, or the angle which each diagonal makes with that which is contiguous, increases without limit, so that, as the diagonals diminish in length, the angles they make with one another become greater than any finite rectilineal angles, and therefore the figure becomes a curve line.

That the lines AC, &c. or the supposed effect of the centrifugal force, diminish as the squares of the times, is evident from the laws of the descent of heavy bodies, as explained under the head of Dynamics.

2. Hence, conversely, if a body move in a curve, so that the line drawn from it to a fixed point describe areas proportional to the times, the body gravitates to that point, or tends continually to descend to it.

Physical Astronomy.

For, since it does not move in a straight line, it must be continually acted on by a deflecting force; and the direction of the deflecting force must always pass through the same point, otherwise the areas described about that point would not be proportional to the time.

3. *Corollary.* The velocities of a body in different points of the curve which it describes about a centre of force, are inversely as the perpendiculars drawn from the centre to the tangents of the curve at these points. Let ACA′, fig. 110, be the curve which a body describes about the centre S. Let A*a* and A′*a*′ be two arches of the curve, described in the same indefinitely small portion of time. Join S*a*, S*a*′, then the areas of the triangles AS*a*, A′S*a*′ are equal by this proposition. At A and A′, draw the tangents AB′ A′B′, and from S let fall on them the perpendiculars SB and SB′. Because the areas of the triangles AS*a*, A′S*a*′, are equal, $Aa \times SB = A'a' \times SB'$, or $Aa : A'a' :: SB' : SB$; but A*a* is to A′*a*′ as the velocity of the body describing the curve at A to its velocity at A, therefore these velocities are inversely as the perpendiculars SB, SB′.

The straight line AB (fig. 109), according to which the projectile motion was impressed on the body, is a tangent to the curve at the point A.

4. On comparing the first and second of these propositions with the first of Kepler's laws, as just enumerated, it is evident that the primary planets all gravitate to the sun, and that the secondary planets gravitate every one to its primary. The next thing, therefore, is to discover the law observed by this force, or the function of the distance to which it is proportional; and also, whether, in that function, other variable quantities are not involved beside the distance. The general fact that the orbits, or curves described by the planets round the sun, are ellipses, may assist in this investigation, and in expressing the velocity of a planet, in terms of the radius vector, or its distance from the sun

5. Let ADBE (fig. 111) be the orbit of a planet, S the focus in which the sun is placed, AB the axis major, and DE the axis minor, C the centre, and F the superior focus. Let the planet be anywhere at P; draw a tangent to the orbit in P, on which from the foci let fall the perpendiculars SG, FH. Draw also DK touching the orbit in D, and let SK be perpendicular to it. Let the velocity of the planet, when at the mean distance, or at D, be $= c$, and when at P $= v$. Join SP, FP. Then, by the corollary to the last proposition, the velocity at D is to the velocity at P as SG to SK, that is, $c : v :: SG : DC$, or $v = c \cdot \frac{DC}{SG}$.

But because the triangles SGP, FHP, are equiangular, having right angles at G and H, and also the angles SPG, FPH equal, from the nature of the ellipse, $SP : PF :: SG : FH$, and therefore also $SP : PF : SG^2 : SG \times FH$. But $SG \times FH = CD^2$, therefore $SP : PF :: SG^2 : CD^2$, and $\frac{CD^2}{SG^2} = \frac{PF}{SP}$. Now $v = c \cdot \frac{CD}{SG}$, or $v^2 = c^2 \cdot \frac{CD^2}{SG^2}$, and therefore $v^2 = c^2 \cdot \frac{PF}{SP}$.

Hence, as the distance of a planet from the sun, at any point in its orbit to its distance from the superior focus, so the square of its velocity at its mean distance from the sun to the square of its velocity at the point just mentioned.

6. If SL be taken in the greater axis equal to SP, and FN $=$ PF, so that SN $=$ the transverse axis AB, $v^2 = c^2 \cdot \frac{NL}{LS} = c^2 \cdot \frac{SN - SP}{SP}$. Then as SN is a given line, v is expressed in terms where SP, the distance from the sun, is the only variable quantity.

Physical Astronomy

If, from the velocity of the revolving body thus expressed in terms of the distance, a transition can be made to that of a body descending in a straight line, the law of the centripetal force will be easily investigated. This will be facilitated by the following proposition:

An equal approach to the centre of force produces an equal increase of the square of the velocity, whether the body revolve in a curve about the centre, or descend to it in a straight line. In like manner, equal recesses from the centre of force produce equal diminutions of the square of the velocities, in whatever lines the bodies move.

Let ABC (fig. 112) be a curve which a body describes about a centre, S, to which it gravitates, while another body descends in a straight line AS, to that centre. Let BC be any arch of the curve ABC, and let BD, CH, be arches of circles described from the centre S, intersecting the line AS in D and H; the square of the velocity of the body, which describes the arch BC, will be as much increased as the square of the velocity of that which falls through DH.

From the centre S describe the arch *bd*, indefinitely near to BD, and draw E*f* perpendicular to the arch B*b*. Also let the centripetal force at B or D be called G. Now, the part of this force which is in the direction B*b*, and which is employed in accelerating the body moving in that line, is $G \times \frac{Bf}{BE}$; and the increment of the space being B*b*, therefore $2G \times \frac{Bf \times Bb}{BE}$ is the momentary increment of the square of the velocity of the body at B. But $Bf \times Bb = BE^2$, because BE*b* is a right-angled triangle, and E*f* the perpendicular on the hypothenuse. Therefore $2\,G \times \frac{Bf \times Bb}{BE} = 2G \times \frac{BE^2}{BE} = 2G \times BE =$ $2G \times Dd$. But $2G \times Dd$ is the momentary increment of the square of the velocity of the body at D, or the increment of that square while the body falls from D to *d*. These momentary increments therefore are equal; and as the same may be shown for the next and every subsequent instant, the whole increase of the square of the velocities of the bodies in moving over BC and DH are equal.

If the bodies moved in the opposite directions, the one from C to B, and the other from H to D, it would be proved, in the same manner, that the squares of their velocities would be equally diminished.

7. Hence it is evident, that, if the velocities of the revolving and of the falling body are equal in any one instance when they are equally distant from the centre, their velocities will always be equal when they are equally distant from that point; for equal quantities receiving equal increments continue equal.

8. Suppose now that a planet revolves in the elliptical orbit APB (fig. 111), it will have at A, the higher apsis, a velocity $= c \times \sqrt{\frac{AF}{AS}}$, or (if AN in the axis produced be taken equal to AF) $= c \times \sqrt{\frac{AN}{AS}}$. Let a body at A begin to descend towards S with the same velocity; then if SL $=$ SP, the velocity of the planet at P will be the same with that of the falling body at L. But the velocity of the planet at P is $c \times \sqrt{\frac{PF}{PS}} = c \times \sqrt{\frac{NL}{SL}}$, therefore, a body descending from A, and falling directly to the sun under the action of the same centripetal force which urges the planet, would at any point L in its fall have its velocity $= c \times \sqrt{\frac{LN}{LS}}$. Hence, at the point N

Physical Astronomy.

its velocity would be equal to 0, or the body must begin to fall from N, in order that its velocity may be everywhere equal to that which the planet has in its orbit, when at the same distance from the sun.

The law, therefore, according to which the planets gravitate is such, *that any body under the influence of the same force, and falling direct to the sun, will have its velocity at any point equal to a certain velocity, multiplied into the square root of the distance it has fallen through, divided by the square root of the distance between it and the sun's centre.*

This is a fact with respect to the law of gravity in the solar system, of which, though there be no direct example, yet is it no less certain than the ellipticity of the planetary orbits, of which it is a necessary consequence.

9. From the law thus found to regulate the velocity of bodies falling in straight lines to the sun, the law of the force by which that velocity is produced may be derived by help of reasoning which is quite elementary.

Let C (fig. 113) be the centre to which the falling body gravitates, A the point from which it begins to fall, and let its velocity at any point B, be to its velocity in the point G, which bisects AC, as $\sqrt{\frac{AB}{BC}}$ to 1; it is required to find the law of the force with which the body gravitates to C.

Let DEF be a curve, such, that if AD be an ordinate or a perpendicular to AC, meeting the curve in D, and BE any other ordinate, AD is to BE as the force at A to the force at B, then will twice the area ABED be equal to the square of the velocity which the body has acquired in B. If, therefore, the velocity at B be v, that at the middle point G being c, $v = c\sqrt{\frac{AB}{BC}}$, by hypothesis, and therefore $2ABED = c^2 \cdot \frac{AB}{BC}$; and since $AB = AC - BC$, $2ABED = c^2 \cdot \frac{AC - BC}{BC} = c^2\left(\frac{AC}{BC} - 1\right)$. For the same reason $2AbED = c^2\left(\frac{AC}{bC} - 1\right)$, and therefore the difference of these areas, or $2BbeE$, that is, $2EB \times Bb = c^2\left(\frac{AC}{bC} - \frac{AC}{BC}\right) = c^2 \cdot \frac{AC \cdot Bb}{BC^2}$. Wherefore, dividing by Bb, $2EB = c^2 \cdot \frac{AC}{BC^2}$; or $EB = c^2 \cdot \frac{AG}{BC^2}$; now c^2 and AG are given, therefore EB is inversely as BC^2, that is, the centripetal force at B is inversely as the square of BC, the distance from the centre of force. *In the planetary system, therefore, the force with which any planet gravitates to the sun varies in the inverse ratio of the square of the distance of the planet from the sun's centre.*

10. The line CG is the same with the mean distance of the planet, in an orbit of which AC is the length of the major axis, and if the gravitation at that distance $= F$, and the mean distance itself $= a$, $F = c^2 \times \frac{a}{a^2} = \frac{c^2}{a}$, or $aF = c^2$.

Let it next be required, the elliptic orbit of a planet being given, to find the time in which the planet will revolve round the sun.

If a be the mean distance, or the semimajor axis, b the semiminor, then πab = the area of the orbit. But as c is the velocity at the mean distance, or the elliptic arch which the planet moves over in a second when it is at D, the vertex of the minor axis, therefore $\frac{1}{2}bc$ is the area described in that second by the radius vector; and since this area is the same for every second of the planet's revolution, therefore the area of the orbit divided by $\frac{1}{2}bc$ will give the number of seconds in which the revolution is completed, which is therefore $= \frac{\pi ab}{\frac{1}{2}bc} = \frac{2\pi a}{c}$, or since $c^2 = aF$, the time of a revolution $= \frac{2\pi a}{\sqrt{aF}} = 2\pi\sqrt{\frac{a}{F}}$.

Physical Astronomy

11. Hence it is easy to compare the times of the revolutions of any two planets of which the mean distances are known. Let t and t' be the times of revolution for two different planets, of which the mean distances are a and a', and the gravitation at those distances F and F', and, by what has just been shown, $t : t' :: \frac{a^{\frac{1}{2}}}{F^{\frac{1}{2}}} : \frac{a'^{\frac{1}{2}}}{F'^{\frac{1}{2}}}$, or $t^2 : t'^2 :: \frac{a}{F} : \frac{a'}{F'}$. But $F : F' :: a'^2 : a^2$, by what is already shown (Art. 9), therefore $t^2 : t'^2 :: \frac{a}{a^2} : \frac{a'}{a^2}$, or $t^2 : t'^2 :: a^3 : a'^3$, *that is, the squares of the times of revolution of any two planets are as the cubes of their mean distances from the sun.* Thus the third law of Kepler is explained by the conclusions deduced from the other two.

12. The share which this third law has in establishing the principle of universal gravitation does not seem to have been always clearly apprehended. From the elliptical orbit of a planet, it is fairly inferred that, over all the circumference of that orbit, gravitation is inversely as the square of the distance from the centre of the sun. That force is shown to be $\frac{c^2a}{x^2}$ (x being the distance from the centre of force), and the same is true of every individual planet; but whether c^2a was a constant quantity, or one which retained the same value through the whole planetary system, could not be known without comparing the periods of different planets with their distances from the sun. It was indeed highly probable that c^2a was a given quantity, or the same for every part of our system; but it could not be considered as a thing demonstrated till the evidence of the third law was introduced.

13. These laws hold of the secondary planets relatively to their primary, just as with the primary planets relatively to the sun. Each system of secondary planets, however, has a different numerator to the fraction which expresses gravity; that is, the quantity c^2a is the same for all the satellites of Jupiter, but it is a different quantity from that which belongs to the satellites of Saturn, and different from that which belongs to the primary planets. The quantity c^2a seems therefore to depend on the central body of each system of planets, and the precise nature of this connection requires to be farther examined into.

14. Let the centripetal force tending to a given centre S be inversely as the squares of the distances, and let the intensity of that force at any given distance from the centre be also given; then, if a body be projected from a given point, with a given velocity, and in a given direction, it is required to determine the conic section which it will describe.

Let the semimajor axis, or the mean distance to be found, $= a$, the semiminor $= b$, the velocity at the distance $a = c$, and at the given distance d let the centripetal force $= f$; and first let the direction of the initial motion be at right angles to the radius vector, so that the point of projection is either the higher or the lower apsis. Let the velocity of the projection $= v$, and the radius vector at the point of projection $= r$.

Because the areas described in equal times are equal,

Physical Astronomy.

$bc = rv$; and if F denote the centripetal force at the distance a, $c^2 = a\,\mathrm{F}$, and $\mathrm{F} = \frac{c^2}{a}$. But $\mathrm{F} = \frac{d^2f}{a^2}$, therefore $\frac{c^2}{a} = \frac{d^2f}{a^2}$, and $c = d\sqrt{\frac{f}{a}}$. Hence, by substituting for c, $bd\sqrt{\frac{f}{a}} = rv$, and $b^2d^2f = ar^2v^2$. But $b^2 = \mathrm{AS} \times \mathrm{SB} = r\,(2a - r)$, wherefore $r\,(2a - r)\,d^2f = ar^2v^2$, and $a = \frac{rd^2f}{2d^2f - rv^2}$. Thus a, the semitransverse axis, and therefore the transverse axis itself, is found; and thence with the focus S and the apsis A, the conic section may be described.

15. The conic section will be a circle, when $a = r$, that is, when $2\,d^2f - v^2r = d^2f$, or when $d^2f = v^2r$, and $v^2 = \frac{d^2f}{r}$.

16. But if $2d^2f = rv^2$, or $v^2 = \frac{2d^2f}{r}$, the denominator vanishes, and a becomes infinite, so that the trajectory is a parabola, of which the focus is S, the vertex A, and the parameter $4r$. *The square of the velocity which determines the trajectory to be a parabola is, therefore, double of the square of the velocity which determines it to be a circle.*

17. When $2d^2f > v^2r$, the value of a is affirmative and the conic section is an ellipsis, and this ellipsis has its higher apsis at A, if $v^2 < \frac{d^2f}{r}$; but when $v^2 > \frac{d^2f}{r}$, and less $\frac{2d^2f}{r}$, A *is the lower apsis.*

18. When v^2 goes beyond this last limit, or when $v^2 > \frac{2d^2f}{r}$, the value of a is negative, and the trajectory becomes an hyperbola.

19. Next, let the body be projected from B (fig. 114) with the velocity v, in the direction BD, oblique to BS. Find the distance from which a body must fall to acquire at B the velocity v, and let OB, taken in SB produced, be equal to this distance; then is SO equal to the major axis. Let BE be drawn, making with BD the same angle that SB makes with BG, and let BE = BO, then is E the higher focus. Produce SE to N, so that SN = SO, and bisect EN in A, then is A the higher apsis; and if SP be made equal to EA, P is the lower apsis, and AP the major axis; and therefore the foci and the major axis being given, the elliptic orbit may be described.

20. From what has been shown at Art. 9, it is evident that the primary planets gravitate to the sun with forces that are inversely as the squares of the distances, and that the secondary gravitate toward the primary, according to the same law. This inference, however, does not apply exactly to the moon, which, being a single satellite, does not by comparison with any other afford a proof that, in bodies revolving round the earth, the squares of the periodic times are as the cubes of the mean distances. The centripetal force at the moon, however, from our knowledge of her periodic time, may be compared with the force of gravity at the earth's surface, and will determine whether that force decreases as we recede from the earth in the inverse ratio of the squares of the distances.

Let a be the distance of the moon from the centre of the earth, r the radius of the earth, g the velocity acquired by a heavy body at the earth's surface by falling during one second; let t be the period of the moon's revolution in seconds, and c the velocity of her motion. Then, by Art. 14, $ac^2 = r^2g$, and therefore $c = r\sqrt{\frac{g}{a}}$.

Now, the circumference of the circle described by the moon is $2\pi a$, and this, divided by c, gives the periodic time of the moon in seconds, or $\frac{2\pi a}{r} \times \sqrt{\frac{a}{g}} = t$, so that $t^2 = \frac{4\pi^2a^3}{r^2g}$, and $a^3 = \frac{r^2gt^2}{4\pi^2}$. Hence $\frac{a^3}{r^3} = \frac{gt^2}{4\pi^2r}$, and $\frac{a}{r} = \left(\frac{gt^2}{4\pi^2r}\right)^{\frac{1}{3}}$. Hence, as g, r, and t are known, we may find $\frac{a}{r}$, or the ratio of the moon's distance to the radius of the earth, which, if it come out the same that it is known to be from observations of the moon's parallax, will prove that the force which retains the moon in her orbit is the same that causes bodies to fall at the surface of the earth, but diminished in the same ratio that the square of the moon's distance is greater than the square of the radius of the earth.

Now $g = 32{\cdot}166$ feet, $r = 3481279{\cdot}4$ fathoms or $20887676{\cdot}4$ feet, and $t = 2360591{\cdot}5$ seconds. Hence $\frac{a}{r} = 60{\cdot}218$.

Now the mean equatorial parallax of the moon is found by observation = 57′ 0″·9, from which the mean distance, in semidiameters of the equator, is found = 59·964.

But it is in mean semidiameters of the earth that the moon's distance is given in the former computation; therefore, to reduce the last measure to the same scale, it must be increased by a 600th part, as the mean radius of the globe is about that much less than the radius of the equator; the distance 59·964 then becomes 60·063, which agrees with the former number to the small fraction ·003 of the earth's radius.

Thus, from the theory of gravity, combined with the time of the moon's sidereal revolution, her distance from the earth is found to within a very small fraction of the whole.

21. *It is therefore a general proposition, derived from the most rigorous induction, that the primary planets gravitate to the sun, and the secondary planets to the primary, with forces which are inversely as the squares of the distances.* But since, in all communication of motion, the re-action is equal to the action, when a planet gravitates to the sun, analogy forces us to conclude that the sun gravitates to the planet, in such a manner, that if the momentary approach of the planet to the sun, and of the sun to the planet, were respectively multiplied by the quantity of matter in those bodies, the products, or the *quantities of motion*, would be equal. Such a mutual tendency, therefore, of the great bodies of our system to the sun, and of the sun to them, doubtless takes place; but whether this be in consequence of an attractive force residing in their centres, as the magnetic force does in certain parts of the loadstone, or if it arise from the mutual attraction of all the particles of the one for all the particles of the other, does not appear from the phenomena hitherto examined. We may, however, observe that the bodies between which this attraction in the inverse ratio of the squares of the distances takes place, are all of a round form, and are either accurately spherical, or nearly approaching to that shape. It will therefore be of use for resolving this question, to inquire whether, if the particles of matter did attract one another with forces inversely as the squares of their distances, the spherical bodies, compounded of such particles, would attract one another according to the same law. If this is found to be the case, it will be reasonable to conclude that the gravitation of large bodies to one another arises from the mutual attraction of their particles to one another.

22. In order to determine the relation between the attraction of a sphere and that of the particles of which it consists, we may consider the sphere as made up of plates

Physical Astronomy.

or *laminæ* infinitely great in number, and infinitely small in thickness. The attraction of each of these is to be estimated, and from thence the attraction of the whole may be computed. Let AFBG (fig. 115), therefore, be a circular plate, of which the centre is C; CE a straight line passing through C, and perpendicular to the plane AFBG; E any particle in that line attracted by each particle of the circular plate, as D, with a force inversely as the square of DE, the distance between the particles; it is required to find the whole force with which E is attracted in the direction EC.

If DC be drawn, the force with which D attracts E in the direction ED is inversely as DE^2 or as $\frac{1}{DE^2}$, and that same force, reduced to the direction EC, is as $\frac{1}{DE^2} \times \frac{EC}{DE} = \frac{EC}{DE^3}$. From the centre C, with the radius DC, let a circle DKH be described, and indefinitely near it the circle *d k h*; then, since every particle in the *ring* of matter contained between these circles has its attraction proportional to $\frac{EC}{ED^3}$, the attraction of the whole ring will be as $\frac{EC}{ED^3}$ multiplied into the number of particles, or into the solidity of the ring. But if EC $= a$, ED $= x$, and AC $= r$, $CD^2 = x^2 - a^2$, and the surface of the ring $= 2\pi x dx$. If then the thickness of the plate AFBG $= m$, the solidity of the ring $= 2\pi m x dx$, and its attraction in the direction EC is $= \frac{2\pi m x dx \times a}{x^3} = \frac{2\pi a m dx}{x^2}$, the integral of which taken so as to vanish when DC $= 0$, or when $x = a$, is $2\pi m - \frac{2\pi m a}{x} = 2\pi m\left(1 - \frac{a}{x}\right)$ = the attraction of the circle DKH. Therefore, when $x =$ AE, the whole attraction of the plate, or the whole force which it exerts on the particle E, is $2\pi m\left(1 - \frac{EC}{EA}\right)$.

23. Next, let ABD (fig. 116) be a circle of which the centre is C, and E a particle of matter anywhere in the diameter AB produced. Draw ED to any point D in the circumference; draw also DC, and let DF be at right angles to AB. Then, when the whole figure revolves about EB, the semicircle ADB will generate a sphere, and DF a circle perpendicular to the plane ABD, and having its centre in F. If all the particles of the sphere attract the particle E with forces inversely as the squares of their distances from it, then, by the last proposition, the attraction of the circular plate, of which the centre is F, will be $2\pi m\left(1 - \frac{EF}{ED}\right)$.

Let CE$=a$, AC$=r$, ED$=x$, EF$=y$, and the attraction above will be $2\pi m\left(1 - \frac{y}{x}\right)$; and if x and y be variable, the quantity m in this formula, or the thickness of the circular plate will be $= dy$, and therefore the attraction of the plate $= 2\pi dy\left(1 - \frac{y}{x}\right)$. In order to integrate this quantity, y must be expressed in terms of x, or x in terms of y.

Now, because AE $= a - r$, and AF $= y - a + r$, FB $= 2r - y + a - r = a + r - y$, and AF $\times$ FB $= (r - a - y)(r + a - y) = r^2 - a^2 + 2ay - y^2 = DF^2 = x^2 - y^2$. Hence $r^2 - a^2 + 2ay = x^2$, or $y = \frac{a^2 - r^2 + x^2}{2a}$, and therefore $dy = \frac{x dx}{a}$. By substituting these values of y and dy in the expresssion for the attraction of the circular plate, that

Physical Astronomy

attraction $= \frac{2\pi x dx}{a}\left(1 - \frac{a^2 - r^2 + x^2}{2ax}\right)$

$= \pi\left(\frac{2axdx - a^2dx + r^2dx - x^2dx}{a^2}\right)$.

But the attraction of this circular plate may be considered as the differential of the attraction of the spherical segment, generated by the revolution of the arch AD, and therefore the integral of the above differential quantity will give the attraction of that segment. Now, this integral $= \pi\left(\frac{ax^2 - a^2x + r^2x - \frac{1}{3}x^3}{a^2}\right) + C$. Here C must be so determined that the integral may be equal to 0, when the arch AD $= 0$, or when $x = y = a - r$. Therefore C $= \pi\left(\frac{\frac{1}{3}a^3 - ar^2 + \frac{2}{3}r^3}{a^2}\right)$; and the attraction

$= \frac{\pi}{a^2}(ax^2 - a^2x + r^2x - \frac{1}{3}x^3 + \frac{1}{3}a^3 - ar^2 + \frac{2}{3}r^3)$.

This is the attraction of the spherical segment generated by the arch AD, and will become equal to that of the whole sphere when AD $=$ the semicircle ADB, or when $x = a + r$. This substitution being made, and the terms reduced, the attraction is found $= \frac{4\pi r^3}{3a^2}$. But $\frac{4\pi r^3}{3}$ is the solid content of the sphere; *therefore the attraction of the sphere, on any particle* E, *is as the quantity of matter in the sphere, divided by the square of the distance of its centre from* E. *Hence also the sphere attracts any particle without it, as if all its matter were united in its centre.* The sphere, it is also obvious, would attract another sphere just in the ratio of its quantity of matter, divided by the distance of the centres of the spheres.

24. Thus, supposing that the particles of matter attract one another with forces which are inversely as the squares of the distances, it is certain that the spherical bodies composed of these particles would do so likewise, or would attract one another with forces directly as their quantities of matter, and inversely as the squares of the distances of their centres. Since, therefore, it has been found that round or spherical bodies, such as the sun and the planets, do attract other bodies with forces that are inversely as the squares of the distances, it is reasonable to suppose that these bodies are composed of particles gravitating towards one another, or attracting one another with forces inversely as the squares of the distances. *Gravitation, therefore, is not to be considered as a force residing in the centres of the planets, but as a force belonging to all the particles of matter, and as universally diffused throughout the universe.*

And as it has been shown that between spherical bodies constituted of such particles, the force of attraction is as the quantity of matter in the attracting body, divided by the square of the distance between its centre and that of the attracted body; if m be the mass or quantity of matter in the former body, and x the distance of the centres, $\frac{m}{x^2}$ is the value of f, the accelerating force with which it attracts the other body.

25. Hence the masses of any two planets which have bodies revolving round them may be compared with one another. Let a and a' be the mean distances at which satellites revolve about any two planets, m and m' the quantities of matter in those planets, t and t' their periods

Physical Astronomy.

of revolution; it has been shown that $t=\frac{2\pi a^{\frac{3}{2}}}{df^{\frac{1}{2}}}=\frac{2\pi a^{\frac{3}{2}}}{m^{\frac{1}{2}}}$,

and consequently $t:t'::\frac{a^{\frac{3}{2}}}{m^{\frac{1}{2}}}:\frac{a'^{\frac{3}{2}}}{m'^{\frac{1}{2}}}$, and $m:m'::\frac{a^3}{t^2}:\frac{a'^3}{t'^2}$.

The masses, therefore, of any two planets are as the cubes of the mean distances at which their satellites revolve, divided by the squares of the periodic times of those satellites.

26. In this way the masses of the four planets which have satellites may be compared with one another, and with the mass of the sun.

When this calculation is undertaken with the requisite data, it is found that, making

Mass of the Sun.....1

that of the Earth..... $=\frac{1}{354936}$

of Jupiter..... $=\frac{1}{1070{\cdot}5}$

of Saturn... ..... $=\frac{1}{3512}$

of Uranus..... $=\frac{1}{17918}$.

Or if we make the mass of the Earth 1, that of the Sun = 329630, of Jupiter 330·6, of Saturn 101·06, and of Uranus 20·3. From this also may be derived the densities of the sun and of the four planets just mentioned. Seen from a distance equal to the mean radius of the earth's orbit, the diameter of the sun subtends an angle of 1923″, that of the earth would subtend 17″·4, of Jupiter 186″·8, of Saturn 177″·7, and of Uranus 74″. The real diameters, therefore, are in the proportion of these numbers, and the bulk in the proportion of their cubes. By dividing the quantities of matter by the bulks, we have the densities; and if that of the earth be 4·713, which is its mean density, that of water being = 1, then

Density of the Sun..... =1·1775
of the Earth..... =4·713
of Jupiter..... =1·1678
of Saturn..... =0·4055
of Uranus..... =1·0348.

The mean density of the earth, in respect of water, is here taken from the experiments made at Schehallien. (*Phil. Trans.* 1811, p. 376.)

27. It has been already observed, that because action is always accompanied by an equal re-action, when the sun attracts a planet, the planet also attracts the sun, and that the velocities impressed on the bodies by their mutual attraction are in the inverse ratio of their masses.

In consequence of this mutual action the sun and the planet must both move, and must describe orbits about their common centre of gravity, the only point which the mutual action of those bodies has no tendency to put in motion.

In the solar system, therefore, the centre of gravity of the whole is the focus about which all the orbits are described. Thus, if C be that centre (fig. 117), S the sun, and P a planet; while P describes the elliptic arch PP′ about C, S describes the arch SS′ similar to PP′, and having to it the ratio that SC has to CP, or the ratio which the mass of the planet has to the mass of the sun.

The true orbits, therefore, are all described about the same immovable point; but the orbit of any of the planets may be referred to the sun as a centre, by supposing a body placed in that centre equal to the sum of the masses of the sun and of the planet. This is true, because the bodies appear to approach one another, or to recede from one another, with a force that is equal to the sum of the forces with which they tend towards their centre of gravity. Thus, if S denote the mass of the sun, and E that of the earth, the distances from the centre being CP and CS, the orbit which each of the two bodies will appear to describe round the other, is that which would be described about an immovable centre C, with a centripetal force $=\frac{S+E}{SP^2}$.

Physical Astronomy.

Thus we have arrived at the knowledge of the principle of UNIVERSAL GRAVITATION, a power which pervades all nature, extending to an unlimited distance, and determining the condition of every body in the universe at any instant, from its state in the former instant, and from the relations in which it stands to all other bodies. Whether this force can be explained upon any principle more general than itself, is yet undecided, though, from the bad success which has hitherto attended all attempts towards that object, it seems probable that such explanation is not within the reach of the human understanding. Thus much, however, we know with certainty, that the law of gravity, as just announced, may be considered as a very accurate expression of all the phenomena of the planetary motions.

SECT. II.—*Of the Forces which disturb the Elliptic Motion of the Planets.*

1. *Of the force by which the Sun disturbs the motion of the Moon round the Earth.*

28. The motion of the moon in an elliptic orbit round the earth is disturbed by the action of the sun: the gravity of the moon to the earth is increased at the quadratures, and diminished at the syzygies; and the areas described by the radius vector, except near these four points, are never exactly proportional to the times.

Let ADBC (fig. 118) be the orbit, nearly circular, in which the moon M revolves, in the direction CADB, round the earth E. Let S be the sun, and let SE, the radius of the earth's orbit, be taken to represent the force with which the earth gravitates to the sun.

Then $\frac{1}{SE^2}:\frac{1}{SM^2}::SE:\frac{SE^3}{SM^2}=$ the force by which the sun draws the moon in the direction MS. Take $MG=\frac{SE^3}{SM^2}$, and let the parallelogram KF be described, having MG for its diagonal, and having its sides parallel to EM and ES. The force MG may be resolved into the two, MF and MK, of which MF, directed towards E, the centre of the earth, increases the gravity of the moon to the earth, and does not hinder the areas described by the radius vector from being proportional to the times.

The other force MK draws the moon in the direction of the line joining the centres of the sun and earth. It is, however, only the excess of this force above the force represented by SE, or that which draws the earth to the sun, which disturbs the relative position of the moon and earth. This is evident, for if KM were just equal to ES, no disturbance of the moon relatively to the sun could arise from it. If, then, ES be taken from MK, the difference HK is the whole force in the direction parallel to SE, by which the sun disturbs the relative position of the moon and earth. Now, if in MK, MN be taken equal to HK, and if NO be drawn perpendicular to the radius vector EM produced, the force MN may be resolved into two, MO and ON, the first lessening the gravity of the moon to the earth; and the second, being parallel to the tangent of the moon's orbit in M, accelerates the moon's motion from C to A, retards it from A to D, and so alternately in the other two quadrants.

Thus the whole solar force directed to the centre of

the earth is composed of the two parts MF and MO, which are sometimes opposed to one another, but which never affect the uniform description of the areas about E. Near the quadratures the force MO vanishes, and the force MF, which increases the gravity of the moon to the earth, coincides with CE or DE. As the moon approaches the conjunction at A, the force MO prevails over MF, and lessens the gravity of the moon to the sun. In the opposite point of the orbit, when the moon is in opposition at B, the force with which the sun draws the moon is less than that with which the sun draws the earth, so that the effect of the solar force is to separate the moon and earth, or to increase their distance; that is, it is the same as if, conceiving the earth not to be acted on, the sun's force drew the moon in the direction from E to B. This force is negative, therefore, in respect of the force at A, and the effect in both cases is to draw the moon from the sun, in a direction perpendicular to the line of the quadratures.

29. The analytical values of these forces must be found if a more exact estimate is to be made of their effects. Let SE, considered as constant, $= a$; EM, the radius vector of the moon's orbit, $= r$; the angle CEM $= \varphi$; the mass of the sun $= m$. The force SE, then, which retains the earth in its orbit, is $\frac{m}{a^2}$, and the sun's force in the direction SM, if ML be drawn perpendicular to ES, is $\frac{m}{SM^2}$ $= \frac{m}{SL^2+LM^2} = \frac{m}{(a-r\sin.\varphi)^2+r^2\cos.\varphi} = \frac{m}{a^2-2ar\sin.\varphi+r^2}$. The part of this force, which is in the direction ES or MK, is therefore $\frac{ma}{(a^2-2ar\sin.\varphi+r^2)^{\frac{3}{2}}}$. By raising the denominator to the power $-\frac{3}{2}$, rejecting the terms which involve the higher powers of r, and multiplying ma by those that are left, the force MK comes out $= \frac{m}{a^2}\left(1+\frac{3r}{a}\sin.\varphi\right)$ nearly. Taking away from this ES or MH $= \frac{m}{a^2}$, there remains the force MN $= \frac{m}{a^3} \times 3r\sin.\varphi$.

Hence the force MO $= \frac{m}{a^3} \cdot 3r\sin.^2\varphi$; and the force NO at right angles to the radius vector $= \frac{m}{a^3} \cdot 3r\sin.\varphi \times \cos.\varphi = \frac{m}{a^3} \cdot \frac{3r}{2}\sin.2\varphi$; also the force MF $= \frac{mr}{a^3}$, rejecting such terms as involve the square and higher powers of r. Therefore MF—MO, or the whole solar force increasing or diminishing at any point, the moon's tendency to the earth is $\frac{mr}{a^3}(1-3\sin.^2\varphi)$.

30. At the quadratures where φ vanishes, this force is $\frac{mr}{a^3}$, and is affirmative, increasing the moon's gravity to the earth. At a certain point, between the quadratures and the syzygies, when $3\sin.^2\varphi = 1$, or $\sin.\varphi = \frac{1}{\sqrt{3}}$, that is, when $\varphi = 35° 15' 5''$, the same force becomes equal to 0, and at this point in each quadrant the moon's gravity to the earth is neither increased nor diminished. From these points to the conjunction and opposition, as $\sin.\varphi$ increases, the quantity $1-3\sin.^2\varphi$ is negative, and the moon's gravity to the earth suffers a diminution. At the opposition and conjunction $\sin.\varphi = 1$, and therefore the disturbing force is $-\frac{2mr}{a^3}$, and by this quantity the moon's gravitation is diminished.

The mean quantity of the force which is thus continually directed to or from the centre of the earth may also be easily computed. Since for any point in the moon's orbit, where the radius vector makes the angle φ with the line of the quadratures, this force $= \frac{mr}{a^3}(1-3\sin.^2\varphi)$; multiplying by $d\varphi$, we have $\frac{mr}{a^3}(d\varphi - 3d\varphi\sin.^2\varphi)$, the integral of which $= \frac{mr}{a^3}(-\frac{1}{2}\varphi + \frac{3}{2}\sin.\varphi\cos.\varphi)$, and this, when φ is an entire circumference or four right angles, is $\frac{mr}{a^3} \times \pi$. This is the sum of the forces for an entire revolution, and when divided by 2π, gives the mean force $-\frac{mr}{2a^3}$ which being negative, shows that the solar force, on the whole, diminishes the gravitation of the moon to the earth.

Thus it appears, that at the quadratures the gravity of the moon to the earth is increased by a quantity equal to the mass of the sun, multiplied into the radius of the moon's orbit, and divided by the cube of the sun's distance from the earth: at the syzygies it is diminished by twice this quantity; and the effect on the whole is a diminution by one half of the same quantity.

If $\frac{mr}{a^3}$ be reduced to its numerical value, supposing the moon's gravitation to the earth to be 1, it is found $= \frac{1}{174}$ nearly. Hence the mean disturbing force of the sun is nearly $= \frac{1}{348}$ of the moon's gravity to the earth.

31. From the disturbing force of the sun arise two kinds of inequalities which affect the lunar motions; the one kind affects the form and position of the orbit of that planet, the other immediately affects the motion of the planet in the orbit. When any of these inequalities is expressed numerically, the measure of it so obtained is, in the language of astronomy, called *an Equation.*

32. The line in which the plane of the moon's orbit cuts the ecliptic is called the line of the nodes; and this line is subject to change its position continually, in such a manner as to go back annually 19° 19′ 42″·3. The way in which this effect is produced may be thus conceived. That part of the solar force which is parallel to the line joining the centres of the sun and earth, is not in the plane of the moon's orbit, except when the sun itself is in that plane, or when the line of the nodes, being produced, passes through the sun. In all other cases it is oblique to the plane of the orbit, and may be resolved into two forces, one of which is at right angles to that plane, and is directed towards the ecliptic. This force of course draws the moon continually towards the ecliptic, or produces a continual deflection of the moon from the plane of her own orbit towards that of the earth Hence the moon meets the plane of the ecliptic sooner than it would have done if that force had not acted. At every half-revolution, therefore, the point in which the earth meets the ecliptic advances in a direction contrary to that of the moon's motion, or contrary to the order of the signs. This retrograde motion is such that, in its mean quantity, it amounts to 19° 19′ 42″·3 in a year. The manner of de-

Physical Astronomy.

ducing it from the theory of gravity is explained by Newton, *Princip.* lib. iii. prop. 31. This motion is subject to many inequalities, depending on the changes in the quantity and direction of the solar force.

If the earth and the sun were at rest, the effect of the deflecting force just described would be to produce a retrograde motion of the line of the nodes till that line was brought to pass through the sun, and of consequence the plane of the moon's orbit to do the same, after which they would both remain in their position, there being no longer any force tending to produce a change in either. The motion of the earth carries the lines of the nodes out of this position, and produces, by that means, its continual retrogradation.

33. The same force produces a small variation in the inclination of the moon's orbit, giving it an alternate increase and decrease within very narrow limits.

34. The line of the moon's apsides, that is, the longer axis of her orbit, has also a slow angular motion round the centre of the earth, which is progressive, or in the same direction with the motions of the moon itself. To conceive the cause of this phenomenon, we may begin with supposing the moon at the lower apsis, or perigee; and it is plain, if that planet were urged by no other force than its gravitation to the earth, that after the *radius vector* had moved over 180°, the moon would be at the higher apsis, where its motion would be at right angles to the said radius. But as the mean disturbing force in the direction of the radius vector tends, on the whole, to diminish the gravitation of the moon to the earth, the portion of her path, described in any instant, will be less bent or deflected from the tangent, than if this disturbing force did not exist. The actual path of the moon, therefore, will be less incurvated than the elliptic orbit that would be described under the influence of gravity alone, and will not be brought to intersect the radius vector at right angles, till this last have moved over an arch of more than 180°.

Hence the solar force, by lessening the moon's gravity to the earth, produces a progressive motion in the apsides of the lunar orbit. If the disturbing force had increased the moon's gravity to the earth, the motion of the apsides would have been *in antecedentia.*

The precise quantity of the motion of the apsides is not however easily determined. Newton left this part of the lunar theory almost untouched; and the only investigation he has entered into having any reference to it, assigned a measure only the half of that which is known from observation to belong to it. Several years afterwards, when Clairaut attempted a more accurate investigation of the lunar inequalities than was to be obtained by the method which Newton had followed, he at first encountered the same difficulty, and found that his calculus gave the motion of the apogee only half of the real quantity. He began, therefore, to suspect that gravity does not follow so simple a law as the inverse of the squares of the distances, but one which is more complex, and such as cannot be expressed but by a formula of two terms. The second of these terms he supposed to be inversely as the fourth power of the distance, and proceeded to inquire what must be the co-efficient of that term, in order to make this new supposition represent the true motion of the apsides. In order to this, he found it necessary to carry his approximation farther than he had yet done, and to include terms which he had before neglected. When these terms were included, he found that the co-efficient he was seeking for came out equal to 0; the necessary inference from which was, that there was no such term; and that the Newtonian law of gravity, when the approximation was carried far enough, was quite sufficient to explain the motion of the apsides. This doubt concerning the law of gravity terminated, therefore, in the confirmation of it. Physical Astronomy

35. When the doubts excited by Clairaut's first attempt were made known, and before his final solution of the difficulty was fully understood, there were several mathematicians who, still following the method of Newton, endeavoured to deduce the true motion of the moon's apsides from the theory of gravity. Among those who were most successful in this attempt were Dom. Walmesley, and afterwards Dr Matthew Stewart, professor of mathematics in the university of Edinburgh. In his *Mathematical and Physical Tracts* he has demonstrated this remarkable theorem:

Let r be the radius of the moon's orbit, supposing it to be a circle, and the moon to be acted on only by F, her gravity to the earth. If the mean disturbing force by which the sun diminishes the moon's gravity be f, then will the greatest distance to which the moon will recede from the earth be $r \times \frac{F-3f}{F-5f}$; and the cube of this distance will be to the cube of r, in the duplicate ratio of the angle described by the moon from one apsis to the same apsis again, to four right angles.

Hence the angle described by the radius vector from one apsis to the same apsis, is $360° \times \left(\frac{F-3f}{F-5f}\right)^{\frac{3}{2}}$.

This proposition, which is demonstrated by Dr Stewart in the fourth of his Tracts, in a manner somewhat prolix, on account of his rigorous adherence to the methods of the ancient geometry, but in a way perfectly clear and elementary, is employed by him to deduce the mean disturbing force from the motion of the apsides as ascertained by observation. But when the mean disturbing force is known from other phenomena, the same proposition may be employed to deduce the motion of the apsides from that force. Accordingly, if the disturbing force be taken $= \frac{1}{357{\cdot}7}$, the motion of the apsides will come out $= 3°\ 1'\ 20''$ for a sidereal revolution of the moon, very near the quantity actually observed.

36. Having determined the sun's mean disturbing force from the motion of the apsides, Dr Stewart proceeded to determine from the former of these the sun's distance from the earth. The result of a very nice investigation gave the sun's parallax $6''{\cdot}9$, a quantity that is no doubt too small, and makes of course the sun's distance too great. It is indeed but an inconsiderable part of the sun's disturbing force into which the parallax enters as an element, and therefore any deduction founded on it must be liable to this inaccuracy, that a small error in the data will produce a great one in the result.

37. After the inequalities which are conceived as belonging to the moon's orbit, come those which directly affect the place of the moon in that orbit. The most considerable of these, after what is called the equation of the centre, arising from the elliptic figure of the lunar orbit, and independent of all disturbance, is the equation or inequality called the evection, which was discovered by the Greek astronomers. This depends on the position of the transverse axis of the moon's orbit in respect of the line of the syzygies. When that axis is in the line just mentioned, because the quantity by which the solar force diminishes the gravitation of the moon in the syzygies is, *cæteris paribus*, proportional to her distance from the earth, it is greatest when the moon is in the apogee, and least when in the perigee. In this situation of the orbit, therefore, the greatest diminution is made from the quantity of the moon's gravitation which is already the least, and

the least from that which is already the greatest; the gravitation at the perigee, and therefore the difference, is augmented, and the orbit appears to have its eccentricity increased. When the line of the apsides is in the quadratures, the contrary happens; the gravitation at the apogee is most augmented, and at the perigee least; the difference is therefore diminished, and the eccentricity of the lunar orbit seems also to be diminished. This is conformable to observation; and when the evection is accurately deduced from the theory of gravitation, it appears $= (1^\circ\ 20'\ 29''{\cdot}9)\ \sin.\left(2\left(\mathrm{☾}-\odot\right)-a\right)$ where ☾ is the mean longitude of the moon, ⊙ that of the sun, and a the mean anomaly of the moon counted from the perigee.

38. The moon's variation is an inequality which was discovered by Tycho, and found to depend on the angular distance of that planet from the sun. It is derived from that part of the sun's disturbing force which is at right angles to the radius vector, and which accelerates the motion of the moon from the quadratures to the syzygies, and retards it from the syzygies to the quadratures. The effect of this force is found, from the theory of gravity, to be represented by three terms, which, if $\triangle$ be the angular distance of the moon from the sun, are,

$$+\ (35'\ 41''{\cdot}9)\ \sin.\ 2\triangle$$
$$+\ (\ 0'\ \ 2''\ \ )\ \sin.\ 3\triangle$$
$$+\ (\ 0'\ 14''\ )\ \sin.\ 4\triangle.$$

39. The lunar inequality, called the annual equation, arises from the variation of the sun's disturbing force according to the place which the earth occupies in its orbit. It is shown above that the sun's disturbing force is, *cæteris paribus*, inversely as the cube of his distance; so that when the earth is in its perihelion this force is the greatest, and at the aphelion the least, its effect varying at the same rate with the equation of the sun's centre, or having everywhere the same ratio to that equation. Hence this equation is nearly $(11'\ 12'') \times$ sin. sun's mean anomaly, with a contrary sign to the equation of the sun's centre.

40. These inequalities are all phenomena which were observed before the explanation of them was known. To them may be added a fourth inequality, known by the name of the moon's acceleration. It appeared to astronomers as a continual increase in the velocity of the moon, or in the rate of her mean motion, amounting to about 10″ in a century, and its effect, like that of all other constant accelerations, accumulating as the squares of the times. It did not seem to be periodical, like the other lunar inequalities, but to be a constant increase of the velocity, and a corresponding diminution of the periodical time of the moon, which must in the end change entirely the relation of that body to the earth.

It is but a short time since Laplace discovered it to be a periodic inequality, though requiring, in order to accomplish the series of its changes, a length of time which science has not yet ventured to calculate. For many centuries to come it may be expressed by this formula, taking n to denote the number of centuries reckoned from the year 1700, viz.,

$$10''{\cdot}7232 \times n^2 + 0''{\cdot}019361 \times n^3.$$

The first term includes all that was known from observation previously to the discovery of Laplace. This, however, must be considered not as the true form of the equation, which must include the sines or cosines of certain angles, but merely a provisional formula, to serve till the true one can be rigorously assigned.

This inequality has in its cause a great affinity to the annual equation.

Whatever changes the form of the earth's orbit, has an effect on the disturbing force of that body on the moon, which is in the inverse ratio of the cube of the distance between the sun and earth. But it is found that though the mean distance remains invariable, the eccentricity of the earth's orbit changes, on account of the action of the other planets, and in fact has been diminishing, from a more remote antiquity than that to which the history of astronomy extends. From this cause Laplace has deduced the supposed acceleration of the moon's mean motion.

41. All these inequalities have been pointed out by observations, and have been explained in the most satisfactory manner by the principle of universal gravitation. But when all these were reduced into equations and arranged in tables, yet the places of the moon calculated from them were never quite exact; and there seemed a cause of error or a mass of small inequalities unknown in their magnitude and form, to which this inaccuracy was to be ascribed, and which operated, as it may be said, like a mist which concealed the true place of the moon from the calculator, and prevented his results from agreeing completely with those of the observer. The most likely way to discover these inequalities, if they arose from gravity, was to push the approximation to the moon's place still farther, and to try if the terms hitherto neglected in the approximation would not, when taken into account, afford a complete analysis of the circle of confusion which might be said to surround the moon on all occasions.

The problem on which mathematicians now entered, and which Clairaut, already mentioned, Euler, and D'Alembert, all three resolved nearly about the same time, has been called the *Problem of Three Bodies*. The thing proposed is, three bodies which attract one another with forces directly as their quantities of matter, and inversely as the squares of their distances, being given, and any motions whatever being impressed on them, to find the orbits which they will describe round their common centre of gravity. It is, however, only in certain cases that this general problem admits of solution, and one of these is, when one of the bodies is at a vast distance from the other two. This is exactly the case with the moon and earth in respect of the sun, the orbit of the earth being nearly the same as if there only existed the sun and earth, and the orbit of the moon relative to the earth being nearly the same if there were only the moon and earth. This solution of the problem, however, in this direct way, leads to far more exact conclusions than can be obtained from the more simple but more indirect method which Newton followed. The general view which leads to the most exact estimate of the merit of the two solutions is, that the motions of the moon, when analytically and fully expressed, necessarily form a number of different series, each of which converges with more or less rapidity. The prosecution of the direct method allows the terms of these series to be computed to an indefinite extent, or till the quantities omitted are too small to affect observation. The method of Newton can go no farther than to compute the first, or at most a few of the leading terms of each of the series. Its accuracy is therefore limited; that of the other knows no limits. Though this be a true estimate of the value of the methods, yet that of the original inventor possesses infinite merit, as having first led the way to this arduous investigation, and as still serving to carry the imagination better along with it than the other, and to keep the mechanical principles more directly in view.

The complete solution of the problem of the *three bodies* has accordingly discovered a great number of new equations, each individually small, which would sometimes nearly destroy one another, and, at other times, having many of them the same sign, would accumulate to a considerable amount. This was the triumph of the theory, and the strongest evidence of its truth. The effect

Physical Astronomy.

of these irregularities varied so much, and depended on so many elements, that it may be doubted whether the most accurate and most constant observation would ever have enabled astronomers to discover their precise quantities, and to separate them from one another.

The tables of the moon, in the state to which they are now brought, contain twenty-eight equations for the longitude, twelve for the latitude, and thirteen for the horizontal parallax of the moon. Of the first of these, twenty-three have been deduced from theory alone; of the second, nine; and of the third, eleven. This applies to the tables of Burg: those since published by Burckhardt contain more equations, and are still more accurate.

2. *Of the Disturbance in the Motion of the Primary Planets, produced by their action on one another.*

42. It is evidently necessary, in this inquiry, to know the quantities of matter in the different planets, or, which comes to the same, the intensity of the attraction of each at a given distance from its centre. With respect to those planets which have satellites, the Earth, Jupiter, Saturn, and Uranus, their masses or quantities of matter have been already determined. The masses of Venus and Mars have been estimated by Laplace, from the effects which they appear to produce on the earth's motion. The mass of Mercury has been estimated on the supposition that the densities of that planet and of the earth are inversely as their mean distances from the sun. This law holds with respect to the Earth, Jupiter, and Saturn, and analogy renders it probable that the same law includes the other planets. Thus, the mass of the Sun being 1, that of Mercury is $\frac{1}{2025810}$, of Venus $\frac{1}{405871}$, and of Mars $\frac{1}{2546320}$; the masses of the other planets being as already stated.

43. The effects of the action of the planets on one another is more difficult to be investigated than the effects of the sun's action on the moon, because the disturbing forces are not only more numerous, but because the distance of the disturbing from the disturbed body is not so great that the quantities divided by higher powers of that distance can be so safely rejected. The general principle, however, according to which the solar action on the moon was resolved into forces either in the direction of the radius vector or at right angles to it, is applicable to both questions.

Thus, supposing P and P′ (fig. 119) to be two planets revolving in orbits, nearly circular, about the sun at S; in order to find how the motion of P′ is affected by the action of P, let PP′, PS, and P′S be drawn, and let the line A denote the force with which P attracts a particle of matter at the distance PS, then the force with which it attracts a particle at the distance PP′, will be $A \times \frac{PS^2}{P'P^2}$. Let $P'R = A \times \frac{PS^2}{P'P^2}$; and if P′R be resolved into two forces, P′M and P′N, the one in the direction of the radius vector P′S, and the other parallel to PS, take NO = A; then the remaining forces OP′ and P′M are those which disturb the motion of P′, as was proved in the case of the moon. The former of these, OP′, may be resolved into OQ and P′Q, of which P′Q diminishes the gravity of the planet to the sun, and OQ accelerates its motion in a direction perpendicular to the radius vector. Therefore, as the force P′M always increases the planet's gravity to the sun, P′M—P′Q is the whole force increasing or diminishing the gravity of P′ to S; and the force directly employed in increasing or diminishing the angular motion of P about S, is OQ or P′T. The analytical values of these quantities may be found, as in the theory of the moon, though not with equal simplicity, because SP cannot always be supposed great in respect of SP′.

44. In consequence of these actions, the orbit of every planet may be considered as an ellipsis, which is undergoing slowly certain changes in its form, magnitude, and position, or in what are called its elements. By the elements of the orbit of any heavenly body, are meant the quantities that determine the position and magnitude of that orbit, viz. the position of the line of the nodes, the inclination of the plane of the orbit to the plane of the ecliptic, the position of the line of the apsides, the eccentricity, and the mean distance. These are all quantities independent of one another, and from them may be deduced all other circumstances with respect to the elliptic orbit. Of these five elements, which would be invariable if the planet only gravitated to the sun, all except the mean distance are subject to slow but perpetual changes.

Physical Astronomy.

45. The line of the nodes, in every one of the planets, has a retrograde angular motion, which goes on continually, and of which the amount, when calculated as due to each planet, agrees very well with observation. The plane of the orbit also varies its inclination, by certain small periodical changes, which alternately increase and diminish it, as in the case of the moon. The line of the apsides, from the same cause as in the planet just mentioned, has a continued motion forward, or according to the order of the signs. Thus, in Mercury the node goes back about 7″·82 annually. The aphelion goes forward about 5″·84 in a year, and the inclination of the orbit in the course of a century increases about 18″·18, which, in the course of succeeding ages, will be compensated by an equal diminution, so as to preserve it always nearly of the same quantity. In the same planet the equation of the centre, which depends on the eccentricity, increases about 1″·6 in a century, indicating a small increase of eccentricity. These variations in the orbit of Mercury arise from the action of Venus, the Earth, Mars, Jupiter, and Saturn; the effects of the first of these planets, on account of its vicinity, being by much the most considerable. The mean distance, however, of Mercury from the Sun, does not, any more than that of the other planets, undergo any change whatever.

46. Similar conclusions apply also to the orbit of Venus. The orbit of the earth also is subject to similar changes, the line of the apsides moving forward annually at the rate of 11″·8, in respect to the fixed stars. The earth's eccentricity is also diminishing, and the secular variation of the greatest equation of the centre is — 17″·66.

The motion of the earth is subject to another inequality on account of the action of the moon; for, to speak strictly, it is not the centre of the earth, but the centre of gravity of the moon and earth, which describes equal areas in equal times about the centre of the sun. It is evident that, on this account, the earth will be sometimes advanced before, and sometimes will fall behind, the point which describes the circumference of the ellipsis, in conformity with the general law of the planetary motions. From the same cause also, as the moon does not move in the plane of the ecliptic, the earth will be forced out of that plane, in order to preserve a position diametrically opposite to the moon. These irregularities, however, are inconsiderable. By observers on the earth's surface, they are transferred to the sun, but in an opposite direction. The sun, therefore, has a motion in longitude, by which he alternately advances before the point which describes the elliptic orbit in the heavens, and falls behind it; and also a motion in latitude, by which he alternately ascends above and descends below the plane of the ecliptic. As the mass of the moon, however, is not more than $\frac{1}{79}$ part of that of the earth, the distance of the centre of gravity of the moon and earth from the centre of the latter must be

less than a semidiameter, and therefore the inequality thus produced in the sun's longitude must be less than his horizontal parallax. The alteration in latitude can hardly amount to a second. This inequality in the sun's motion is called the menstrual parallax, and was first mentioned by Smeaton, *Phil. Trans.* 1768.

47. In the orbit of Mars the node moves backward 23″·3 annually, and the line of the apsides moves forward 15″·8, both in respect of the fixed stars. The eccentricity of the orbit is increasing, and the secular variation of the greatest equation of the centre is + 37″.

In the case of this planet, however, the elliptic orbit is not only changed by these quantities, but the place of the planet in that orbit is sensibly affected by the action of Venus, Jupiter, and the Earth. The effect of the action of Venus is expressed by this formula, 5″·7 sin. (long. ♀ — 3 long. ♁); of the earth, 7″·2 sin. (long. ☉ — long. ♀). Several inequalities are produced in Jupiter.

48. The inequalities of the small planets *Vesta, Juno, Ceres,* and *Pallas*, have also been computed. The disturbances which they must suffer from Venus, Mars, and Jupiter are considerable, and, on account of their vicinity, though their masses are small, they may somewhat disturb the motions of one another. Their action on the other bodies in the system is probably insensible.

As Pallas and Ceres have nearly the same periodic time, they must preserve nearly the same distance and the same aspect with regard to one another. This offers a new case in the computation of disturbing forces, and may produce equations of longer periods than are yet known in our system.

The motion of the apsides and the change of eccentricity in the orbits of Jupiter and Saturn are chiefly produced by their action on one another, but a part also depends on the action of the other planets. The node of Jupiter moves backward annually 15″·8, and his aphelion forward 6″·96. The secular change in the inclination of the orbit is 22″·6, and in the first and last of these inequalities the action of Venus has the principal share. The equation of the centre increases 56″·25 in a century, of which nearly the whole arises from the action of Saturn. In Saturn again the node goes back at the rate of 19″·4 annually, and the aphelion forward at the rate of 19″·4; the secular change of the inclination is — 15″·5, and the secular diminution of the equation of the centre 2′·1.

There is, besides these variations in the orbits, an inequality in the motion of each of these planets, which for a long time was difficult to explain, and was ultimately fully accounted for, according to the theory of gravity, by the profound investigations of Laplace. These inequalities are both of a long period, viz. 918·76 years, which is the time that they take to run through all their changes. If n express a number of years reckoned from the beginning of 1750, S the mean longitude of Saturn, and I that of Jupiter, reckoned from the same time, then the equation which must be applied to the mean longitude of Jupiter, or the amount of this inequality, is

$$+ (20' 49''{\cdot}5 - n \times 0''{\cdot}042733) \times \sin.(5\,S - 2\,I + 5^\circ\ 34'\ 8'' - n \times 58''{\cdot}88);$$

and that which must be applied to S is

$$-(48'\ 44'' - n \times 0''{\cdot}1) \times \sin.(5\,S - 2\,I + 5^\circ\ 34'\ 8'' - n \times 58''{\cdot}88).$$

These two equations are to one another nearly in the ratio of 3 to 7. The reason of the long period above mentioned is, that the argument $5\,S - 2\,I - n \times 58''{\cdot}88$ requires all that time to increase from 0 to 360°.

Uranus, on account of his great distance, suffers hardly any disturbance in his motion, but from Saturn and Jupiter. The node moves backward at the rate of 36″ annually, and the aphelion forward at that of 2″·55. The eccentricity is diminishing, and the secular variation of the greatest equation of the centre is 11″·03.

There is also an inequality in the longitude of this planet, depending on the action of Saturn. If S be the longitude of this last planet, U the longitude of Uranus, and A the longitude of the aphelion of Saturn, the inequality in question amounts to 2′ 30″ × sin. (S — 2 U + A).

49. *Of all these inequalities, and of many other smaller ones which theory has discovered, it must be observed that they are periodical, each returning after a certain time to run through the same series of changes which it had formerly exhibited.*

Another remark is, that one element in every orbit, viz. the mean distance, is exempted from all excepting periodical changes; and since on the mean distance depends the time of revolution, that time remains also unchanged. From the invariability of the mean distance, and the periodical revolution of all the inequalities, it follows that the actual condition of the planetary system can never deviate far from the mean, about which we may, therefore, conceive it to be continually making small oscillations, which in the course of ages compensate one another, and therefore produce nothing like disorder or permanent change. It is in this manner that the stability of the planetary system is provided for by the wisdom of its Author.

50. *Comets*, in describing their elliptic orbits round the sun, have been found to be disturbed by the action of the larger planets, Jupiter and Saturn; but the great eccentricity of their orbits makes it impossible, in the present state of mathematical science, to assign the quantity of that disturbance for an indefinite number of revolutions, though it may be done for a limited portion of time, by considering the orbit as an ellipsis, the elements of which are continually changing. This is the method of Lagrange, and is followed in the *Mécanique Céleste*, Part ii. chap. ix. Dr Halley, when he predicted the return of the comet of 1682, took into consideration the action of Jupiter, and concluded that it would increase the periodic time of the comet a little more than a year; he therefore fixed the time of the re-appearance to the end of the year 1758, or the beginning of 1759. He professed, however, to have made this calculation hastily, or, as he expresses it, *levi calamo*. (*Synopsis of the Astronomy of Comets.*)

The effects both of Jupiter and Saturn on the return of the same comet were afterwards calculated more accurately by Clairaut, who found that it would be retarded 511 days by the action of the former planet, and 100 by the action of the latter; in consequence of which, the return of the comet to its perihelion would be on the 15th of April 1759. He admitted at the same time that he might be out a month in his calculation. The comet actually reached its perihelion on the 13th of March, just 33 days earlier than was predicted; affording, in this way, a very striking verification of the theory of gravity, and the calculation of disturbing forces. The same comet appeared again, according to prediction, in 1835.

In some instances, the effect which the planets produce on the motion of comets are far more considerable than in this example. A comet which was observed in 1770 had a motion which could not be reconciled to a parabolic orbit, but which could be represented by an elliptic orbit of no great eccentricity, in which it revolved in the space of five years and eight months. This comet, however, which had never been seen in any former revolution, has never been seen in any subsequent one. On tracing the path of this comet, Mr Burckhardt found that between the year 1767 and 1770 it had come very near to Jupiter, and had done so again in 1779. He therefore conjectured, that the action of Jupiter may

Physical Astronomy.

have so altered the original orbit as to render the comet for a time visible from the earth; and that the same cause may have so changed it, after one revolution, as to restore the comet to the same region in which it had formerly moved. This is the greatest instance of disturbance which has yet been discovered among the bodies of our system, and furnishes a very happy, as well as an unexpected, confirmation of the theory of gravity.

Though the comets are so much disturbed by the action of the planets, yet it does not appear that their reaction produces any sensible effect. The comet of 1770 came so near to the earth as to have its periodic time increased by 2·246 days, according to Laplace's computation; and if it had been equal in mass to the earth it would have augmented the length of the year by not less than two hours and forty-eight minutes. It is certain that no such augmentation took place, and therefore that the disturbing force by which the comet diminished the gravity of the earth is insensible, and the mass of the comet, therefore, less than $\frac{1}{500}$th of the mass of the earth. The same comet also passed through the system of the satellites of Jupiter without causing any derangement of their motions. Hence it is reasonable to conclude, that no material or even sensible alteration has ever been produced in our system by the action of a comet.

3. *Of the disturbances which the satellites of Jupiter suffer from their action on one another.*

51. The same resolution of the forces by which one satellite acts upon another, into two, one directed to the centre of the primary, and the other at right angles to it, serves to explain the irregularities which had been observed in their motions, and to reduce under known laws several other inequalities, of which the existence only is indicated by observation.

An instance of this we have in the very remarkable relation which takes place between the mean motions of the first three satellites; the mean motion of the first satellite, together with twice the mean motion of the third, being equal to three times the mean motion of the second. Laplace has shown that, if the primitive mean motions of these satellites were nearly in this proportion, the mutual action of these bodies on one another must in time have brought about an accurate conformity to it.

The first moves nearly in the plane of Jupiter's equator, and the orbit has no eccentricity, except what is communicated from the third and fourth, the irregularities of one of these small bodies producing similar irregularities in those that are contiguous to it. The first satellite has, beside, an inequality, chiefly produced by the action of the second, and circumscribed by a period of 437·659 days.

52. The plane of the orbit of the second satellite is inclined to a determinate fixed plane at an angle of 27′ 13″, and on which its nodes have a retrograde motion, so that they complete a revolution in 29·914 years. The motion of the nodes of this satellite is one of the principal data used for determining the masses of the satellites themselves, which are so necessary to be known for computing their disturbances. This satellite has no eccentricity but that which it derives from the action of the third and fourth. The plane of the orbit of the third satellite is inclined to a determinate fixed plane at an angle of 12′ 20″, and its nodes make a tropical revolution backwards in 141·739 years. The equator of Jupiter is inclined to the plane of his orbit at an angle of 3° 5′ 30″. The fixed planes on which the planes of the orbits move are determined by theory, and could not have been discovered by observation alone.

The orbit of the third satellite is eccentric, but appears to have two distinct equations of the centre; one which really arises from its own eccentricity, and another which theory shows to be an *emanation* from the equation of the centre of the fourth satellite. The first equation is referable to an apsis which has an annual motion of 2° 36′ 39″ forward in respect of the fixed stars; the second equation is referable to the apsides of the fourth satellite.

Physical Astronomy.

These two equations may be considered as forming one equation of the centre, referable to an apsis that has an irregular motion. The two equations coincided in 1682, and the sum of their *maxima* was 13′ 16″. In 1777 the equations were opposed, and their difference was 5′ 6″.

The two last inequalities were perceived by Mr Wargentin, by observation alone; but their exact amount, and the law which they observe in their changes, he could not discover. The plane of the orbit of the fourth satellite is inclined to a determinate fixed plane at an angle of 14′ 58″; and its nodes complete a sidereal revolution backward in 531 years. The fixed plane on which the orbit moves is inclined at an angle of 24′ 33″ to the equator of Jupiter; the orbit is sensibly elliptical, and its greater axis has an annual motion of 42′ 58″·7. The motion of this axis is one of the principal data from which the quantities of matter of the different satellites have been determined.

If the mass of Jupiter be supposed unity, the mass of

the 1st satellite = ·0000173281
of the 2d = ·0000232355
of the 3d = ·0000884972
of the 4th = ·0000426591

If the mass of the earth be supposed unity, that of the third satellite will be found = ·027337; and as the mass of the moon is $\frac{1}{79·89}$ = ·012517, the quantity of matter in the third satellite is about twice as great as that in the moon. The fourth satellite is therefore nearly equal to the moon, the second about one half, and the first somewhat more than one third.

53. The general result of this investigation concerning the inequalities in the motion of the planets, both primary and secondary, is, that in every one of these orbits two things remain secure against all disturbance, the mean distance and the mean motion, or, which is the same, the transverse axis of the orbit, and the time of the planet's revolution. Another result is, that all the inequalities in the planetary motions are periodical, and observe such laws that each of them, after a certain time, runs through the same series of changes. This last conclusion follows from the fact, that every inequality is expressed by terms of the form A sin. *nt* or A cos. *nt*, where A is a constant co-efficient, and *n* a certain multiplier of *t* the time, so that *nt* is an arch of a circle, which increases proportionally to the time. Now, in this expression, though *nt* is capable of indefinite increase, yet, since *nt* never can exceed the radius, or 1, the maximum of the inequality is A. Accordingly, the value of the term A sin. *nt* first increases from 0 to A, and then decreases from A to 0; after which it becomes negative, extends to — A, and passes from thence to 0 again. If, when the inequality was affirmative, it was an addition to the mean motion, when negative it will become a diminution of it; and the sum of all these increments and decrements, after *nt* has passed over an entire circumference, or 360°, is equal to 0; so that at the end of that period the planet is in the same position as if it had moved on regularly all the while at the rate of the mean motion. As this happens to every one of the inequalities, the deviation of the system from its mean state can never go beyond certain limits, each inequality in a certain course of time destroying its own effect.

It would be far otherwise if into the value of any inequalities a term entered of the form A × *nt*, A tan. *nt*.

Practical Astronomy.

$\frac{A}{\sin. nt}$. The inequalities so expressed would continually increase with the time, so as to go beyond any assignable limit, and of consequence to destroy entirely the order of any system to which they belonged.

Lagrange and Laplace, who discovered and demonstrated that no such terms as these last can enter into the expression of the disturbances which the planets produce by their action on one another, made known one of the most important truths in physical science. They proved that the planetary system is stable, and that it does not involve any principle of destruction in itself, but is calculated to endure for ever, or till the action of an external power shall put a period to its existence. After the knowledge of the principle of gravitation, this may be fairly considered as the greatest discovery to which men have been led by the study of the heavens.

The accurate compensation, just remarked, depends on three conditions, belonging to the primitive or original constitution of our system, but not necessarily determined, as far as we know, by any physical principle. The first of these conditions is, that the eccentricities of the orbits are all inconsiderable, or contained within very narrow limits, not exceeding in any instance one tenth or one eighth part of the mean distance. The second condition is, that the planets all move in the same direction, or from west to east. This is true both of the primary and secondary planets, with the exception only of the satellites of Uranus, which may be accounted retrograde; but their planes being nearly at right angles to the orbit of their primary, the direction of their motion, whether retrograde or otherwise, can have little effect. Lastly, the planes of the orbits of the planets are not much inclined to one another. This is true of all the larger planets, though it does not hold of some of the new and smaller ones; of which, however, the action on the whole system must be altogether insensible. Practical Astronomy

Unless these three conditions were united in the constitution of the solar system, terms of the kind just mentioned, admitting of indefinite increase, might enter into the expression of the inequalities, which would indicate a gradual and unlimited departure from the original order and constitution of the universe. Now, the three conditions just enumerated do not necessarily arise out of the nature of motion, or of gravitation, or from the action of any physical cause with which we are acquainted. Neither can they be considered as arising from chance; for the probability is almost infinity to one, that, without a cause particularly directed to that object, such a conformity could not have arisen in the motions of so large a number of bodies, scattered over the whole extent of the solar system. *The only explanation, therefore, which remains is, that all this is the work of intelligence and design, directing the original constitution of our system, and impressing such motions on the parts as are calculated to give stability to the whole.* (J. P.)

For some further discussions connected with *Physical Astronomy*, see the articles COMETS; EARTH, *Figure of*; PRECESSION of the EQUINOXES; and TIDES.

PART IV.

PRACTICAL ASTRONOMY.

INTRODUCTION.

PRACTICAL ASTRONOMY may be considered as comprehending the observations which must originally have been made to determine the facts which have now been embodied in a system, as well as those which are constantly being made for its further extension and improvement; the observations which are required to make the science useful in the affairs of life; and the rules and calculations which must be applied to the observations, to obtain from them the required results.

Of the first class of observations mentioned above, the most important are those which relate to general surveys of the heavens, and the extension of cosmical research amongst those bodies that lie beyond the solar system. The sweeps of the stars, and the observations of the nebulæ begun by Sir W. Herschel in the last century, have been carried forward with additional vigour in this. Star maps and star catalogues for almost every portion of the heavens have been accumulating during the present century, till the places and magnitudes of very nearly one hundred thousand stars have been accurately laid down; speculation has closely followed practice; and not only has our own position with respect to the star cluster of which our solar system forms a part, been pretty accurately defined, but clearer views have been obtained of the probable distances and even of the constitution of some others of those systems which, though seen by us under the aspect of a feeble nebulous light, scarcely larger than the apparent disk of a planet of our system, yet probably occupy individually a space equivalent to that of our galaxy, and fill the firmaments of other worlds like our own, with their light and their glory.

Even with regard to observations connected with the solar system merely, observation and theory combined have achieved conquests, since the last edition of this work was published, not inferior in interest or importance. Since the beginning of the present century, the telescope, aided by the improved methods of modern research, has discovered twenty-two of those small fragmentary bodies moving in planetary orbits between Mars and Jupiter; and theory alone, without the aid of the telescope, using only the laws of mechanical action and the results of previous observation, has extended the bounds of the known solar system, by predicting the place of a new body, and calling in the aid of the observer only to verify the fact, and to assist in the inquiry. The assumed well-marked distinction between the planetary and cometary orbits has been disproved by the discovery of several comets moving in ellipses with a periodical term shorter than that of Jupiter; curious physical facts have been elicited by the motions of some of them, while several new members of this class of bodies are yearly added to the list, and their orbits eagerly computed by new aspirants for astronomical fame.

Yet while the science has been thus followed up in its more speculative departments with all the success that the united zeal, talent, and energy of a highly intellectual age would give us reason to expect, and with an accuracy of detail in the observations which brings into play all the resources of mere *practical* astronomy, it has been cultivated with equal ability in those departments to which the term practical more peculiarly belongs, and has lent its aid to the kindred and dependent science of navigation in a way which will soon render the art of guiding a ship through the trackless ocean as perfect both in theory and practice as anything depending upon human casualties can possibly be. The problem of determining the position of a ship at sea depends upon three things mainly, namely, 1*st*, an accurate knowledge of the lunar orbit, and the consequent motions of the moon; 2*dly*, upon the indisputable accuracy of the places of certain fundamental stars and bright planets with which her place is compared; and, 3*dly*, upon the accuracy of performance of chronometers and nautical observing instruments. Now, in all these departments, the progress towards perfection during the last twenty years has been immense. The lunar orbit has been nearly cleared of all its theoretical irregularities, or those depending

Practical Astronomy

upon unknown causes of perturbation, and, very recently, important errors in the tables ordinarily in use have been detected, and corrected; ephemerides of the motions of the moon are computed with all attainable accuracy both in England and America; and finally, by the extra-meridional observations begun at Greenwich in 1847, and continued without intermission to the present time, the errors due to want of observations in certain parts of the orbit (those near conjunction namely) will be altogether got rid of. Again, the Greenwich Catalogues alone furnish the places of large numbers of stars with an accuracy indispensable for lunar purposes only in the case of a few, and every fundamental result of observations connected with the theory of the moon is supplied from the Greenwich Observatory with an accuracy and a steadiness even now unrivalled. Finally, the construction of chronometers and of nautical instruments has been brought to almost as much perfection as the case will admit of. Our government has encouraged the artists to place in competition every year a certain number of chronometers; and the ingenuity of this whole class of persons, brought to bear upon this branch of art, has been the means of eliciting some important improvements in the methods of compensating for temperature and in general construction, at the same time that their rivalry has been the means of reducing the price of the article, and bringing it more within the reach of the ordinary merchant captains of vessels. Various improvements have been at the same time made in surveying instruments and hydrographical methods. The sextant has been simplified and improved; charts have been made of almost every shore in our dominions; the tides have been studied with that attention to the union of high analytical investigations, and the practical results of observations, which have put astronomy on so sound a basis; the laws of the currents of various seas have recently been made the subject of special investigation on a scale equal to its importance; and, in fact, there is not a single branch of nautical astronomy which has not been benefited in an equal degree with the more theoretical or elevated branches of the science.

The science of electricity, in its application to the electric telegraph, has been already of considerable service to astronomy, by affording the opportunity of making simultaneous signals at any two observatories situated on a line of railway, however distant they may be from each other. By this means the differences of longitude of three principal British observatories—namely, Greenwich, Cambridge, and Edinburgh—have already been obtained with an accuracy unattainable by any other method, and the difference of longitudes of Greenwich and Oxford will shortly be determined. The galvanic connexion between Greenwich and Paris is also complete, by means of the submarine communication between Dover and Calais; and experiments will shortly be tried for the determination of the difference of longitudes of these two observatories; and, after this has been accomplished, there will be no difficulty whatever in determining the longitudes of all the continental observatories situated near the grand lines of railroad or telegraph wires. Hopes are beginning to be entertained also of carrying a wire across the Atlantic, and thus bringing the American observatories into connexion with Europe; and the project is not in reality very chimerical.

We need not dwell specifically upon the means by which these great results have been attained. Our two supplements historical and theoretical will have given ample information concerning every available source of improvement in the methods of making observations, and of the chief improvements which have been devised by the eminent men conducting the establishments which have been described. There is scarcely a discovery of importance, or a new method deserving of explanation, in any one of the branches of pure astronomy, concerning which the reader will not find information, and guidance for future research; many of the books which the accomplished astronomer, as well as the student, will require for his pursuit of the science are indicated, and some account of the contents of some of them, where it is necessary to elucidate the subject, has been given.

Such information, indeed, as relates exclusively to the allied sciences of surveying and navigation, must of course be sought for under their respective titles, since the space allotted us would not allow of the extension which such subjects would have required; but, in everything that relates to the observations made in fixed observatories, and to the results deduced from them as applied to the use of these sciences, it is hoped that some instruction has been given. Practical Astronomy

There is one subject which we hoped to have entered into with more minuteness, but which we are prevented from doing through want of space, namely the method of reducing as well as making the observations necessary for the determination of the position of a body in the heavens; and we were the more reluctant to relinquish our design because it is a subject on which most elementary books are either deficient or silent. It has been stated again and again, that the two elements which determine the position in question, are the right ascension and declination of the body, and the instruments which ordinarily determine these elements are the transit instruments (assisted by an astronomical clock) and the mural circle, if two instruments be used, or the transit circle, if only one instrument be employed. Under this head it has been deemed sufficient to retain the accounts of the transit instrument constructed by Troughton for Sir James South, which is still mounted and in excellent condition; and of Troughton's mural circle, erected at the Royal Observatory of Greenwich, in 1812, which was used with excellent effect till the end of the year 1850, when it was replaced by the great transit circle now in use. Each of these instruments is probably one of the best existing specimens of its class, and neither has been excelled in perfection of workmanship even to the present time. In addition to the instruments which determine the place of a body by observations made on the meridian, a third instrument, namely the equatorial, is necessary for various purposes, but especially for comparing planets and comets, of which a sufficient number of observations cannot be obtained on the meridian, with neighbouring stars; of this class of instruments we have retained the accounts of the celebrated Dorpat telescope already mentioned in the account of that observatory, and of the three-foot equatorial in the possession of Sir James South, which was used with such effect by him and Sir John Herschel in the measurement of double stars.

With regard to the tables printed in this department, we have retained those relating to the calculation of eclipses, as interesting to the student, though it must be borne in mind that much better elements exist at present for such calculations than those which were used in these tables.

The catalogue of stars has been replaced by a more modern catalogue accurately compiled, by the use of the best elements, from the Greenwich Twelve-Year Catalogue of 2156 stars. This list includes all the stars down to the fifth magnitude inclusive, which are found in that catalogue, and the places are reduced to the epoch 1850, by the use of the geometrical precessions given in the *British Association Catalogue*, and by the proper motions given in Mr Main's paper on Proper Motions, (*Memoirs of the Royal Astronomical Society*, vol. xix.) Where no proper motion is given by Mr Main,—that is for stars not observed by Bradley or not given in the *Fundamenta*,—the annual variation is taken altogether from the *British Association Catalogue*, except in a few cases specified in the notes.

Finally, we have retained, as useful to the student, the small table of refractions given in the former edition, not as insisting upon its accuracy (since the whole subject has been since revised by Bessel), but as enabling the student to see by compendious tables and examples how this element of correction is taken account of in the reduction of observations.

A few problems given in the former edition have been retained, as being good exercises for the students, and amongst the most interesting and important that belong to the science of plane astronomy, though it is evident that in the systematic study of the science they should be read in their proper order in works treating of the details of the science.

CHAP. I.

PROBLEMS IN PRACTICAL ASTRONOMY.

PROBLEM I.—*Given the right ascension and declination of a star or planet, together with the obliquity of the ecliptic, to find the star's longitude and latitude.*

Let P (fig. 120, Plate XC.) be the pole of the equator O ♈ Q, E the pole of the ecliptic I ♈ L, and S the place of the star. Let PR, the circle of latitude passing through

S, meet the equator in R; and EM, the circle of declination, meet the ecliptic in M; also let ♈E, ♈P, be arcs of great circles passing through the equinoctial point ♈ and the poles of the ecliptic and equator respectively. Let us now make

L = ♈M the longitude of S,
l = SM the latitude,
$\mathcal{A}$R = ♈R the right ascension,
D = SR the declination,
ω = L♈Q the obliquity of the ecliptic.

Since ♈M = ♈L − ML = 90° − ML, and ML is the measure of the angle SEP, we have ♈M = L = 90° − SEP, and, consequently, sin. L = cos. SEP. Again, since ♈R = ♈Q − RQ = 90° − RQ, and RQ is the measure of the angle RPQ, we have ♈R = $\mathcal{A}$R = 90° − RPQ; whence sin. $\mathcal{A}$R = cos. RPQ = − cos. EPS. In like manner we have l = SM = 90° − ES, whence sin. l = cos. ES; and also D = SR = 90° − PS, whence sin. D = cos. PS. Thus the problem depends on the solution of the oblique angled spherical triangle PES.

From the known properties of spherical triangles, we have

cot. PS sin. EP = cot. PES sin. EPS + cos. EP. cos. EPS;

therefore, by substituting the values just found, and observing that EP = ω, we have

tan. D sin. ω = tan. L cos. $\mathcal{A}$R − cos. ω sin. $\mathcal{A}$R;

whence

$$\text{tan. L} = \frac{\text{tan. D sin. } \omega + \text{sin. } \mathcal{A}\text{R cos. } \omega}{\text{cos. } \mathcal{A}\text{R}}.$$

Assume an angle φ such that tan. φ = sin. $\mathcal{A}$R cot. D, then

$$\text{sin. D tan. } \varphi = \text{sin. } \mathcal{A}\text{R cos. D},$$

$$\text{or tan. D} = \frac{\text{sin. } \mathcal{A}\text{R}}{\text{tan. } \varphi} = \frac{\text{sin. } \mathcal{A}\text{R cos. } \varphi}{\text{sin. } \varphi};$$

whence, by substituting,

$$\text{tan. L} = \text{tan. } \mathcal{A}\text{R} \left(\frac{\text{sin. } \omega}{\text{tan. } \varphi} + \text{cos. } \omega\right),$$

and by reducing,

$$\text{tan. L} = \frac{\text{sin. } (\omega + \varphi)}{\text{sin. } \varphi} \text{tan. } \mathcal{A}\text{R} \quad \text{.....(1.)}$$

a formula from which the longitude L is easily computed by means of the logarithmic tables.

To find the latitude l, we have

cos. ES = cos. EP cos. PS + sin. EP sin. PS cos. EPS,

which gives

sin. l = cos. ω sin. D − sin. ω cos. D sin. $\mathcal{A}$R.

Assume as before, tan. φ = cot. D sin. $\mathcal{A}$R, then, by substituting,

sin. l = sin. D (cos. ω − sin. ω tan. φ),

that is,

$$\text{sin. } l = \text{sin. D} \left(\frac{\text{cos. } \omega \text{ cos. } \varphi - \text{sin. } \omega \text{ sin. } \varphi}{\text{cos. } \varphi}\right),$$

whence

$$\text{sin. } l = \frac{\text{sin. D cos. } (\omega + \varphi)}{\text{cos. } \varphi} \quad \text{.....(2.)}$$

PROBLEM II.—*Given the longitude and latitude of a star or planet, together with the obliquity of the ecliptic, to determine its right ascension and declination.*

The spherical triangle EPS gives the relation

cot. ES sin. EP = cot. EPS sin. PES + cos. EP cos. PES,

that is,

tan. l sin. ω = − tan. $\mathcal{A}$R cos. L + cos. ω sin. L,

whence

$$\text{tan. } \mathcal{A}\text{R} = \frac{\text{cos. } \omega \text{ sin. L} - \text{tan. } l \text{ sin. } \omega}{\text{cos. L}}.$$

Assume tan. ψ = sin. L cot. l; then

$$\text{tan. } l = \frac{\text{sin. L}}{\text{tan. } \psi} = \frac{\text{sin. L cos. } \psi}{\text{sin. } \psi};$$

and by substituting this value of tan. l in the above equation, it becomes

$$\text{tan. } \mathcal{A}\text{R} = \text{tan. L} \left(\text{cos. } \omega - \text{sin. } \omega \frac{\text{cos. } \psi}{\text{sin. } \psi}\right),$$

that is,

$$\text{tan. } \mathcal{A}\text{R} = \text{tan. L} \frac{(\text{cos. } \omega \text{ sin. } \psi - \text{sin. } \omega \text{ cos. } \psi)}{\text{sin. } \psi}$$

whence

$$\text{tan. } \mathcal{A}\text{R} = \frac{\text{tan. L sin. } (\psi - \omega)}{\text{sin. } \psi} \quad \text{..... .....(1.)}$$

To find the declination, we have

cos. PS = cos. EP cos. ES + sin. EP sin. ES cos. PES;

that is,

sin. D. = cos. ω sin. l + sin. ω cos. l sin. L,
= (cos. ω + sin. ω cot. l sin. L) sin. l,

and by substituting $\frac{\text{tan. } \psi}{\text{sin. L}}$ for cot. l,

sin. D = (cos. ω + sin. ω tan. ψ) sin l,

$$= \frac{(\text{cos. } \omega \text{ cos. } \psi + \text{sin. } \omega \text{ sin. } \psi) \text{ sin. } l}{\text{cos. } \psi},$$

therefore

$$\text{sin. D} = \frac{\text{cos. } (\psi - \omega)}{\text{cos. } \psi} \text{ sin. } l \quad \text{.....(2.)}$$

Corollary.—In the case of the sun, the latitude l becomes zero, and the formulæ are considerably simplified. Thus, let T be the sun's place in the ecliptic; the relations subsisting between the longitude, right ascension, declination, and obliquity, are given by means of the right-angled spherical triangle ♈TR. The following are the formulæ:

$$\left.\begin{aligned} \text{sin. L} &= \frac{\text{sin. D}}{\text{sin. } \omega}, \\ \text{tan. L} &= \frac{\text{tan. } \mathcal{A}\text{R}}{\text{cos. } \omega}, \end{aligned}\right\} \quad \text{.....(1.)}$$

$$\left.\begin{aligned} \text{sin. } \mathcal{A}\text{R} &= \text{cot. } \omega \text{ tan. D}, \\ \text{tan. } \mathcal{A}\text{R} &= \text{cos. } \omega \text{ tan. L}, \end{aligned}\right\} \quad \text{.....(2.)}$$

$$\left.\begin{aligned} \text{sin. D} &= \text{sin. } \omega \text{ sin. L} \\ \text{tan. D} &= \text{tan. } \omega \text{ sin. } \mathcal{A}\text{R}, \end{aligned}\right\} \quad \text{.....(3.)}$$

PROBLEM III.—*Given the latitude of the observatory, the polar distance of a star, and its hour-angle at the pole, to find its zenith distance, azimuth, and angle of variation.*

Let P (fig. 121) be the pole of the equator, A the zenith of the place, and V the position of the star: we have then given the two sides, AP and PV, of an oblique angled spherical triangle, together with the included angle APV, to determine the third side and the remaining angles.

Make λ = AP the complement of the latitude,
Δ = PV the polar distance of the star, which is here supposed to be north,
P = APV the hour-angle at the pole,
Z = AV the zenith distance,
A = VAP the azimuth,
V = AVP the angle of variation.

1. To find Z we have

cos. Z = cos. λ cos. Δ + sin. λ sin. Δ cos. P.

Assume tan. φ = tan. Δ cos. P; then by substituting,

cos. Z = cos. Δ (cos. λ + sin. λ tan. φ);

whence, by reducing,

Practical Astronomy.

$$\cos. Z = \cos. \Delta \frac{\cos.(\lambda - \varphi)}{\cos. \varphi} \quad \ldots\ldots\ldots (1.)$$

2. To find A, we have from spherical trigonometry the formula

$$\cot. A = \frac{\cot. \Delta \sin. \lambda}{\sin. P} - \cot. P \cos. \lambda.$$

Assume $\cot. \psi = \frac{\cot. \Delta}{\cos. P}$, whence $\cot. \Delta = \cot. \psi \cos. P$, and, by substituting,

$$\cot. A = \cot. P (\cot. \psi \sin. \lambda - \cos. \lambda)$$
$$= \cot. P \left(\frac{\cos. \psi \sin. \lambda - \sin. \psi \cos. \lambda}{\sin. \psi}\right),$$

whence

$$\cot. A = \frac{\cot. P \sin.(\lambda - \psi)}{\sin. \psi} \quad \ldots\ldots\ldots (2.)$$

3. To find V we have

$$\cot. V = \frac{\cot. \lambda \sin. \Delta}{\sin. P} - \cos. \Delta \cot. P.$$

Assume $\cot. \chi = \frac{\cot. \lambda}{\cos. P}$, or $\cot. \lambda = \cot. \chi \cos. P$, then, by substituting and reducing as above, we have

$$\cot. V = \frac{\cot. P \sin.(\Delta - \chi)}{\sin. \chi} \quad \ldots\ldots\ldots (3.)$$

PROBLEM IV.—*Given the declination and zenith distance of a star, and the latitude of the observatory, to determine the hour-angle.*

This is the case in the solution of spherical triangles, in which the three sides are given to find one of the angles. The formula, therefore, from which P is computed (see SPHERICAL TRIGONOMETRY) is

$$\tan.^2 \tfrac{1}{2} P = \frac{\sin. \frac{1}{2}(Z + \lambda - \Delta) \sin. \frac{1}{2}(Z - \lambda + \Delta)}{\sin. \frac{1}{2}(Z + \lambda + \Delta) \sin. \frac{1}{2}(\lambda + \Delta - Z)}$$

PROBLEM V.—*Given the latitude of a place, and the sun's declination, to find, 1st, the time of sunrise; 2d, the sun's amplitude at rising; 3d, the time when the sun is due east; 4th, the sun's altitude when in that position.*

In fig. 122 let AZP be the meridian, in which Z is the zenith, and P the pole; let ZO be the prime vertical, and AOB the horizon, A being the south, O the east, and B the north points; let SS′ be the part of the parallel described by the sun between his rising and passing the prime vertical, and PS PS′ hour circles.

Let L = the latitude of the place = PB,
D = the sun's declination = 90° — PS,
v = the time from midnight to sunrise = hour angle SPB,
x = the sun's amplitude at rising = OS,
y = the time from midnight to the sun's coming on the prime vertical = hour-angle S′PB,
z = the sun's altitude when in the prime vertical = OS′.

In the spherical triangle PBS, right angled at B,

$$\cos. SPB = \frac{\tan. PB}{\tan. PS}, \quad \cos. BS = \frac{\cos. PS}{\cos. PB};$$

and in the spherical triangle PZS′, right angled at Z,

$$\cos. ZPS = \frac{\tan. PZ}{\tan. PS'}, \quad \cos. ZS' = \frac{\cos. PS'}{\cos. PZ}.$$

Now PB = L, PZ = 90° — L, PS = PS′ = 90° — D, BS = 90° — x, ZS′ = 90° — z; hence we have these four formulæ:

$$\cos. v = \tan. L, \tan. D \quad \ldots\ldots\ldots (1.)$$
$$\sin. x = \frac{\sin. D}{\cos. L} \quad \ldots\ldots\ldots (2.)$$
$$\cos. y = \cot. L, \tan. D \quad \ldots\ldots\ldots (3.)$$
$$\sin. z = \frac{\sin. D}{\sin. L} \quad \ldots\ldots\ldots (4.)$$

Practical Astronomy.

The hour-angles v and y must be converted into time by allowing 15° to one hour.

PROBLEM VI.—*To find how much the rising of the sun or a star is advanced by refraction.*

Let ZPB be the meridian (fig. 123), Z the zenith, P the pole, and OB the horizon. Let SS′, the parallel described by the sun, meet the horizon in S. Were it not for the effect of refraction, the sun or star would appear to rise at S, and at rising the hour-angle from midnight would be SPB; but it is elevated by refraction (which takes place in a vertical circle), and appears to rise at D, while in fact it is below the horizon at S′ somewhere in the vertical circle ZD produced downward, and the time of rising is accelerated by the small angle SPS′.

Let L denote the latitude of the place = 90 — PZ; D the declination of the star = 90 — PS; H the hour-angle BPS, reckoned from midnight; r the arc DS of the vertical ZS, the effect of refraction; and x the angle SPS, the acceleration of time of rising.

In the spherical triangle ZPS′,

$$\cos. ZS' = \cos. ZP \cos. PS' + \sin. ZP \sin. PS' \cos. ZPS',$$

Now, $\cos. ZS' = \cos.(90 + r) = -\sin. r$,
and $\cos. ZPS' = -\cos. BPS' = -\cos.(H - x)$;

therefore

$$-\sin. r = \sin. L \sin. D - \cos. L. \cos. D \cos.(H - x).$$

In like manner, in the triangle ZPS, in which $\cos. ZS = \cos. 90° = 0$,

$$0 = \sin. L \sin. D - \cos. L \cos. D \cos. H;$$

hence, by subtraction,

$$\sin. r = \cos. L \cos. D\,[\cos.(H - x) - \cos. H],$$

and $$\cos.(H - x) - \cos. H = \frac{\sin. r}{\cos. L \cos. D};$$

but $\cos.(H - x) - \cos. H = 2 \sin. \frac{1}{2} x \sin.\left(H - \frac{x}{2}\right)$ (ALGEBRA, § 240, D);

therefore, $2 \sin. \frac{1}{2} x \sin.\left(H - \frac{x}{2}\right) = \frac{\sin. r}{\cos. L \cos. D}$.

Now, x and r being small angles, we may consider $2 \sin. \frac{1}{2} x = x$, $\sin. r = r$, and $\sin.\left(H - \frac{x}{2}\right) = \sin. H$.

We have then $$x = \frac{r}{\sin. H \cos. L \cos. D};$$

and here H is determined by the formula

$$\cos. H = \tan. L \tan. D.$$

The value of x just found is only a near approximation; let it be denoted by x', and let $H' = H + x'$, and we shall have more nearly

$$x = \frac{r}{\sin. H' \cos. L \cos. D}$$

Since $\cos. H = \tan. L \tan. D = \frac{\sin. L \sin. D}{\cos. L \cos. D}$,

therefore, $$\sin.^2 H = \frac{\cos.^2 L \cos.^2 D - \sin.^2 L \sin.^2 D}{\cos.^2 L \cos.^2 D}.$$

Again, $\cos.^2 L \cos.^2 D - \sin.^2 L \sin.^2 D$
$= (\cos. L \cos. D - \sin. L \sin. D)(\cos. L \cos. D + \sin. L \sin. D)$
$= \cos.(L + D) \cos.(L - D)$.

Practical Astronomy

Therefore, $\sin.^2 H = \frac{\cos.(L+D)\cos.(L-D)}{\cos.^2 L \cos.^2 D}$,

and $x = \frac{r}{\sqrt{[\cos.(L+D)\cos.(L-D)]}}$.

The value of r is variable; but in general it is about 33 minutes of a degree, or 132 seconds of time. Therefore the acceleration by refraction is nearly, in time,

$$\frac{132^s}{\sqrt{[\cos.(L+D)\cos.(L-D)]}}.$$

PROBLEM VII.—*To find the length of the twilight.*

Let ZPB (fig. 123) be the meridian, Z the zenith, P the pole, and SDB the horizon. Let S'S be the arc of the parallel described by the sun between the beginning of the twilight, when he is at S', and its end at sunrise, when he reaches the horizon at S.

The twilight begins when DS', the sun's depression below the horizon, is about 18°.

Let a denote the arc, DS the depression, L the latitude of the place = 90° — ZP, D the sun's declination = 90° — PS, H the hour angle SPB (from midnight), x the angle SPS'.

Then, cos. ZS' = cos. ZP cos. PS' + sin. ZP sin. PS' cos. ZPS';

that is, because cos. ZS' = — sin. a, and cos. ZPS = — cos. SPB,

— sin. a = — sin. L sin. D — cos. L cos. D cos. (H — x);

hence we obtain

$$\cos.(H-x) = \tan. L \tan. D + \frac{\sin. a}{\cos. L \cos. D}.$$

Now, by Problem V. cos. H = tan. L tan. D.....(1)

Let φ be such an angle, that

$$\cos.\varphi = \frac{\sin. a}{\cos. L \cos. D};$$

Then cos. (H — x) = cos. H + cos. φ

= 2 cos. $\frac{1}{2}$ (H + φ) cos. $\frac{1}{2}$ (H — φ)..... ..(2)

Now H is determined by formula (1); therefore x, the angle described about the pole while the twilight lasts, is determined by formula (2).

PROBLEM VIII.—*Given the right ascensions and declinations of two celestial bodies, to compute their angular distance.*

Let S and M (fig. 124) be the two stars (for example the sun and moon), and let Z be the zenith, and P the pole of the equator. In the triangle SPM, the side SM represents the angular distance of the two stars; PS and PM are respectively their polar distances, or the complements of their declinations, and therefore given; and the angle SPM is also given, being the difference of ZPS and ZPM, the right ascensions of the given stars. Let PS = Δ, PM = Δ', the angle SPM = P, and SM, the distance sought, = d. We have then

cos. d = cos. Δ cos. Δ' + sin. Δ sin. Δ' cos. P.

Assume tan. φ = tan. Δ cos. P; then, by substituting and reducing, as in Problem II., we obtain

$$\cos. d = \frac{\cos.\Delta \cos.(\Delta' - \varphi)}{\cos.\varphi}.$$

PROBLEM IX.—*To determine the latitude of a place.*

1. Of the various methods which are employed for determining the latitude, that which depends on the observation of the double transits, or upper and lower culmination of a circumpolar star, is perhaps the best, being independent of the star's declination, and of the effects of aberration and nutation. The accuracy of the result depends, indeed, on the allowance made for refraction; but unless the observed star at the lower culmination passes within 15° or 20° of the horizon, the errors of the tables will be very inconsiderable. Practical Astronomy.

Let Z be the observed zenith distance, and R the refraction of the star at its lower culmination; Z' and R' the same quantities at its upper culmination, and λ the correct zenith distance of the pole, or the co-latitude; then

$$\lambda = \tfrac{1}{2}(Z + Z') + \tfrac{1}{2}(R + R').$$

The quantities R and R' must be taken from the tables, regard being had to the state of the barometer and thermometer.

2. Another method of determining the latitude, which, by reason of the facility of observation and computation, is extremely commodious, and therefore much employed, especially by voyagers, depends on observations of the meridional zenith distances of the sun or a star. Let P (fig. 125) be the pole, Z the zenith, C the intersection of the meridian and equator, and S the sun or star; then, l being the required latitude,

$$l = ZC = ZS \pm SC = Z \pm D,$$

according as the star is situated S or S', that is, above or below the equator.

If the star is to the north of the zenith, and above the pole, as at a, then

$$l = ZC = Ca - Za = D - Z,$$

and if below the pole, at a', then $Ca' = 180° - D$, and

$$l = ZC = Ca' - Za' = 180° - (Z + D).$$

PROBLEM X.—*To determine the difference of longitude between two points on the earth's surface.*

The different methods which have been proposed for the solution of this problem, one of the most difficult in practical astronomy, are the following: 1*st*, The eclipses of Jupiter's satellites; 2*d*, the eclipses of the moon; 3*d*, the eclipses of the sun; 4*th*, the occultations of fixed stars by the moon; and, 5*th*, the comparison of the moon's transits over the meridian with those of certain fixed stars selected for the purpose. Of these five methods, the two first give results affected by many causes of uncertainty; and the third can seldom be practised, because solar eclipses occur very rarely for any given point on the earth's surface. Of the remaining two, the last (which is recommended by Mr Baily) seems entitled to the preference, on account of its being independent of great accuracy in the rate of the clock or the position of the transit instrument.

The difference of the longitudes of the two stations is supposed to be *nearly* known from the chronometer, or by other means; and the object is to correct or determine the error of the first approximation.

Let A and B be the two stations, of which A is supposed to be the most *westerly*, and put

r = the difference (in sidereal time) of the transit of the moon's limb and the star previously agreed on at A;

r' = the same difference at B;

t = the *apparent* Greenwich time of the culmination of the moon at A;

t' = the *apparent* Greenwich time of the culmination of the moon at B;

d = ☽'s true declination, r = ☽'s true radius } computed for the time t;

d', r' = the same quantities computed for the time t';

s = the length of the true solar day in seconds;

m = ☽'s motion in ☌R in half that interval, expressed in seconds of space;

Practical Astronomy.

χ = the assumed difference of longitude, in time;
$(\chi + e)$ = the correct difference of longitude.

The angle comprised between the two horary circles which pass respectively through the centre and limb of the moon, at the station A, is $\frac{r}{\cos. d}$, which being reduced to time, becomes $\frac{r}{15 \cos. d}$, and expresses the sidereal time in which the moon's semi-diameter passes the meridian. Hence $r \mp \frac{r}{15 \cos. d}$ is the observed difference of the $\mathcal{A}$R of the star and moon's centre at A, the upper sign being taken when the first or western limb of the moon is observed, and the under when it is the eastern limb, the star being supposed to precede the moon. In the same manner $\frac{r'}{15 \cos. d'}$ is the sidereal time in which the semi-diameter of the moon passes the meridian at B, and $r \mp \frac{r'}{15 \cos. d'}$ the observed difference of the $\mathcal{A}$R of the star and moon's centre. We have, therefore, by subtracting these two expressions,

$$(r - r') \mp \frac{r}{15 \cos. d} \mp \frac{r'}{15 \cos. d'}$$

for the observed difference of the $\mathcal{A}$R of the moon's centre, during the time elapsed between the two observations. Put this difference equal to Δ, then $\chi + \Delta$ is the difference between t and t' in sidereal time, which becomes $(\chi + \Delta) \frac{8640}{s}$ when expressed in mean solar time. Hence we have

$$t = t' + (\chi + \Delta) \frac{8640}{s};$$

consequently, when the apparent Greenwich time at one of the observatories is known, it is also known at the other observatory. Now, let a and a' be the moon's $\mathcal{A}$R in *space*, computed for the times t and t' respectively (taken from the ephemeris); then the formula for the correction of the assumed difference of longitudes will evidently be

$$e = \left\{15 \Delta - (a - a')\right\} \frac{s}{2m};$$

and this added to χ gives $\chi + e$, the corrected difference of longitudes.

PROBLEM XI.—*To find the meridional zenith distance of the sun (or a star), from observations made near the meridian.*

Let P (fig. 124) be the pole, Z the zenith, and S the sun. Make

l = 90° — PZ = the latitude of the place;
D = 90° — PS = the declination;
P = ZPS the hour angle;
Z = l — D = the true zenith distance;
Z' = ZS the observed zenith distance;
x = Z' — Z the correction.

The triangle PZS gives

cos. ZS = cos. ZP cos. PS + sin. ZP sin. PS cos. ZPS,
or cos. Z' = sin. l sin. D + cos. l cos. D cos. P;
but cos. (l — D) = cos. l cos. D + sin. l sin. D,
and cos. P = 1 — 2 sin.^{2} $\frac{1}{2}$ P,

therefore,

cos. Z' = cos. (l — D) — 2 cos. l cos. D sin.^{2} $\frac{1}{2}$ P,
or cos. Z' = cos. Z — 2 cos. l cos. D sin.^{2} $\frac{1}{2}$ P.

Now, by the trigonometrical formula (ALGEBRA, § 240),

cos. Z — cos. Z' = 2 sin. $\frac{1}{2}$ (Z' — Z) sin. $\frac{1}{2}$ (Z' + Z),

therefore,

2 sin. $\frac{1}{2}$ (Z' — Z) sin. $\frac{1}{2}$ (Z' + Z) = 2 l cos. D sin.^{2} $\frac{1}{2}$ P.

Practical Astronomy

But Z' — Z = x, and Z' + Z = 2 Z + x,

therefore,

2 sin. $\frac{1}{2}$ x sin. (Z + $\frac{1}{2}$ x) = 2 cos. l cos. D sin.^{2} $\frac{1}{2}$ P,

that is,

2 sin. $\frac{1}{2}$ x cos. $\frac{1}{2}$ x sin. Z + 2 sin.^{2} $\frac{1}{2}$ x cos Z
= 2 cos. l cos. D sin.^{2} $\frac{1}{2}$ P,
or 2 sin. $\frac{1}{2}$ x cos. $\frac{1}{2}$ x + 2 sin.^{2} $\frac{1}{2}$ x cot. Z
$= \frac{2 \cos. l \cos. D}{\sin. Z}$ sin.^{2} $\frac{1}{2}$ P.

In order to resolve this equation, make cot. Z = a. $\frac{\cos. l \cos. D}{\sin. Z}$ sin.^{2} $\frac{1}{2}$ P = b, and divide both sides by 2 cos.^{2} $\frac{1}{2}$ x; it then becomes

$$\tan. \tfrac{1}{2} x + a \tan.^2 \tfrac{1}{2} x = \frac{b}{\cos.^2 \frac{1}{2} x} = b (1 + \tan.^2 \tfrac{1}{2} x).$$

Whence

$$\tan.^2 \tfrac{1}{2} x + \frac{1}{a - b} \tan. \tfrac{1}{2} x = \frac{b}{a - b};$$

and, consequently,

$$\tan. \tfrac{1}{2} x = -\frac{1}{2(a - b)} \mp \frac{1}{2(a - b)} \sqrt{1 + 4 b(a - b)}.$$

Developing this expression, and rejecting all the powers of b higher than the cube, we have

$$\tan. \tfrac{1}{2} x = b - ab^2 + (1 + 2a^2) b^3 —, \&c.$$

Now the series which expresses the arc in terms of its tangent (see art. ALGEBRA, § 270), gives

$$\tfrac{1}{2} x = \tan. \tfrac{1}{2} x - \tfrac{1}{3} \tan.^3 \tfrac{1}{2} x + \tfrac{1}{5} \tan.^5 \tfrac{1}{2} x —, \&c.$$

Therefore, by substituting, and rejecting the terms containing higher powers of b than the cube,

$$\tfrac{1}{2} x = b - ab^2 + (\tfrac{2}{3} + 2a^2) b^3 —, \&c.$$

that is,

$$x = 2b - 2ab^2 + (\tfrac{4}{3} + 4a^2) b^3 —, \&c.$$

and therefore, on restoring the values of a and b, and dividing by sin. 1″,

$$x = 2\left(\frac{\cos. l \cos. D}{\sin. Z}\right) \cdot \frac{\sin.^2 \frac{1}{2} P}{\sin. 1''} - 2 \cot. Z \left(\frac{\cos. l \cos. D}{\sin. Z}\right)^2 \frac{\sin.^4 \frac{1}{2} P}{\sin. 1''} + 4(\tfrac{1}{3} + \cot.^2 Z) \left(\frac{\cos. l \cos. D}{\sin. Z}\right)^3 \frac{\sin.^6 \frac{1}{2} P}{\sin. 1''} —, \&c.$$

The last term of this series is scarcely sensible in any case; it is therefore only necessary to compute the first two.

If, instead of eliminating Z' by means of the equation Z' — Z = x, we had eliminated Z, the resulting expression would have been

$$x = -2\left(\frac{\cos. l \cos. D}{\sin. Z'}\right) \cdot \frac{\sin.^2 \frac{1}{2} P}{\sin. 1''} + 2 \cot. Z' \left(\frac{\cos. l \cos. D}{\sin. Z'}\right)^2 \frac{\sin.^4 \frac{1}{2} P}{\sin. 1''} —, \&c.$$

PROBLEM XII.—*Given the times of two observed equal altitudes of the sun, to find the true time of his meridional passage.*

Let P (fig. 126) be the pole, Z the zenith, ZPM the meridian, and A and C the places of the sun, before and after his meridional passage, when his zenith distances ZA and ZC are observed to be equal. In consequence of the variation of the sun's declination while he passes from A to C, the hour angles APM and MPC are unequal. Make BPM = APM = P, and let BPC be denoted by φ. Now, APC = 2P + φ; half of which is P + $\frac{1}{2}\varphi$; therefore the true time of the meridional passage will be found by subtracting $\frac{1}{2}\varphi$ from the mean of the times of observed equal altitudes.

To find the value of φ, we have the equation

cos. ZA = cos. ZP cos. PA + sin. ZP sin. PA cos. APM,

Practical Astronomy.

that is (employing the denominations of last problem),

$$\cos. Z = \sin. l \sin. D + \cos. l \cos. D \cos. P \ldots\ldots (1)$$

Now, let $\Delta = B\delta$ be the small change of declination corresponding to the variation of the hour-angle from P to $P + \varphi$, and let $D + \Delta$ be substituted for D, and $P + \varphi$ for P in this equation. It then becomes

$$\cos. Z = \sin. l \sin. (D + \Delta) + \cos. l \cos. (D + \Delta) \cos. (P + \varphi).$$

But as Δ and φ are very small arcs, their cosines may be made equal to the radius, and their sines equal to the arcs themselves; therefore, on expanding the above equation, it becomes

$$\cos. Z = \sin. l \sin. D + \cos. l \cos. D \cos. P + (\sin. l \cos. D - \cos. l \sin. D \cos. P)\,\Delta - \cos. l \cos. D \sin. P. \varphi. + \cos. l \sin. D \sin. P. \Delta. \varphi;$$

whence, in consequence of equation (1), and rejecting the term multiplied by $\Delta . \varphi$,

$$(\sin. l \cos. D - \cos. l \sin. D \cos. P)\,\Delta = \cos. l \cos. D. \sin. P. \varphi;$$

therefore,

$$\varphi = \Delta\left(\frac{\tan. l}{\sin. P} - \tan. D \cot. P\right).$$

Let t be the sidereal time of the first observation, t' that of the second, and $t' - t = 2\theta$. Also let the diurnal variation of D be denoted by v, expressed like the arcs φ and Δ in seconds; we have then $24^h : 2\theta :: v : \Delta$, whence $\Delta = \frac{1}{12}\theta v$, and consequently

$$\varphi = \tfrac{1}{12}\theta v\left(\frac{\tan. l}{\sin. P} - \tan. D \cot. P\right).$$

Now, to convert φ into seconds of time, it is only necessary to divide the number to which it is equal by 15; therefore, expressed in *time*, φ becomes

$$\varphi = \tfrac{1}{180}\theta v\left(\frac{\tan. l}{\sin. P} - \tan. D \cot. P\right).$$

For the angle P we may substitute θ (half the time elapsed between the two observations) converted into degrees, and suppose D to be the value of the declination at the instant of the meridional passage; the value of φ being so small as not to be affected by these substitutions. Therefore, ultimately,

$$\tfrac{1}{2}\varphi = \tfrac{1}{360}\theta v\left(\frac{\tan. l}{\sin. \theta} - \tan. D \cot. \theta\right),$$

which, subtracted from θ, gives the true time of the meridional passage.

PROBLEM XIII.—*To compute the angle of the vertical, or the difference between the* apparent *and* geocentric *latitude arising from the spheroidal figure of the earth* (fig. 127).

Let AMP be a quadrant of the elliptic meridian, C being the centre, and P the pole. The straight line VME, perpendicular to the ecliptic in M, determines the apparent zenith V of the place M, while ZMC drawn through C determines the true zenith Z. Hence the angle ADM is the apparent latitude of M, and ACM its geocentric latitude; and the angle ZMV between the true and apparent zenith is the angle of the vertical.

Let x and y be the rectangular co-ordinates of the point M, the origin being at C, and make $AC = m$, $CP = n$, $ADM = l$, and $ZMV = v$.

The equation of the ellipse gives

$$y^2 = n^2 - \frac{n^2}{m^2} x^2,$$

whence

$$y dy = -\frac{n^2}{m^2} x dx;$$

therefore,

$$\frac{y}{x} = -\frac{n^2}{m^2} \cdot \frac{dx}{dy}.$$

But $\frac{y}{x} = \tan. ACM$, and $-\frac{dx}{dy} = \tan. ADM = \tan. l$; Practical Astronomy

therefore $\tan. ACM = \frac{n^2}{m^2} \tan. l$. Now $ZMV = DMC = ADM - ACM$, therefore $\tan. ZMV = \tan. (ADM - ACM) = \frac{\tan. ADM - \tan. ACM}{1 + \tan. ADM \tan. ACM}$; that is,

$$\tan. v = \frac{\left(1 - \frac{n^2}{m^2}\right)\tan. l}{1 + \frac{n^2}{m^2} \tan.^2 l} = \frac{(m^2 - n^2) \tan. l}{m^2 + n^2 \tan.^2 l}$$

$$= \frac{(m^2 - n^2) \sin. l \cos. l}{m^2 \cos.^2 l + n^2 \sin.^2 l} = \frac{(m^2 - n^2) \sin. l \cos. l}{m^2 - (m^2 - n^2) \sin.^2 l}$$

Now, let $m - n = 1$, or $n = m - 1$; then, by substituting,

$$\tan. v = \frac{(2m - 1) \sin. l \cos. l}{m^2 - (2m - 1) \sin.^2 l}$$

or, neglecting the terms multiplied by $\frac{1}{m^2}$, and recollecting that $\sin. l \cos. l = \frac{1}{2} \sin. 2l$,

$$\tan. v = \frac{\sin. 2l}{2m}\left(2 - \frac{1}{m}\right)\frac{1}{1 - \frac{2}{m} \sin.^2 l},$$

whence

$$\tan. v = \frac{\sin. 2l}{2m}\left(2 - \frac{1}{m}\right)\left(1 + \frac{2}{m} \sin.^2 l\right);$$

that is,

$$\tan. v = \frac{\sin. 2l}{m}\left(1 - \frac{1}{2m} + \frac{2}{m} \sin.^2 l\right)$$

$$= \frac{\sin. 2l}{m}\left(1 - \frac{1}{2m} + \frac{1}{m} - \frac{1}{m} \cos.^2 l + \frac{1}{m} \sin.^2 l\right).$$

but $\cos.^2 l - \sin.^2 l = \cos. 2l$; therefore,

$$\tan. v = \frac{\sin. 2l}{m}\left(1 + \frac{1 - 2 \cos. 2l}{2m}\right);$$

and $2 \sin. 2l \cos. 2l = 4 \sin. 4l$, therefore,

$$\tan. v = \frac{\sin. 2l}{m} + \frac{\sin. 2l - \sin. 4l}{2m^2}.$$

The last term of this expression cannot in any case amount to 2″, so that the angle of the vertical is very nearly proportional to the sine of twice the latitude.

PROBLEM XIV.—*To compute the parallax of the moon, or a planet, in altitude.*

Let P = the horizontal parallax,
p = the parallax of altitude,
Z = the apparent zenith distance.

It was shown in Chap. I. Sect. 2 of THEORETICAL ASTRONOMY that $\sin. p = \sin. P \sin. Z$; now let Z' = the true zenith distance, then $Z = Z' + p$, and consequently

$$\sin. p = \sin. P \sin. (Z' + p)$$
$$= \sin. P (\sin. Z' \cos. p + \cos. Z' \sin. p),$$

therefore

$$\tan. p = \sin. P (\sin. Z' + \cos. Z' \tan. p)$$
$$\tan. p (1 - \sin. P \cos. Z') = \sin. P \sin. Z',$$

whence

$$\tan. p = \frac{\sin. P \sin. Z'}{1 - \sin. P \cos. Z'}.$$

But by a well-known series,

$$p = \tan. p - \tfrac{1}{3} \tan.^3 p + \tfrac{1}{5} \tan.^5 p -, \text{ \&c.}$$

Substituting therefore the above expression for tan. p, and reducing the powers to series, we find

$$p = \frac{\sin. P \sin. Z'}{\sin. 1''} + \frac{\sin.^2 P \sin. 2Z'}{\sin. 2''} + \frac{\sin.^3 P \sin. 3Z'}{\sin. 3''}, \text{ \&c.}$$

Practical Astronomy.

The first two terms of this series are in every case sufficient for the computation of p.

PROBLEM XV.—*To compute the parallax in right ascension.*

In fig. 128 let P be the pole, Z the zenith, A the true place of the moon or a planet, depressed on the vertical circle through the effects of parallax to B. Having joined PA and PB by arcs of great circles, the corresponding variation in right ascension will be represented by the angle APB. Make

P = the horizontal parallax;
p = AB, the parallax of altitude;
Π = APB, the parallax in right ascension;
l = 90° — ZP, latitude of place;
Δ = PA, the polar distance;
N = ZA, the true zenith distance;
N + p = ZB, the apparent zenith distance;
H = ZPA the hour angle.

In the parallactic triangle APB we have

sin. PA : sin. AB : : sin. ABP : sin. APB;

that is,

sin. Δ : sin. p : : sin. ABP : sin. Π,

but sin. p = sin. P sin. (N + p). See THEORETICAL ASTRONOMY, Chap. I. Sect. 2.

Therefore,

$$\sin.\,\Pi = \frac{\sin.\,P\,\sin.\,(N+p)\,\sin.\,ABP}{\sin.\,\Delta}$$

Now, in the triangle ZBP, we have

sin. ZB : sin. ZP : : sin. ZPB : sin. ZBP (ABP);

that is,

sin. (N + p) : cos. l : : sin. (H + Π) : sin. ABP.

Therefore,

$$\sin.\,ABP = \frac{\cos.\,l\,\sin.\,(H+\Pi)}{\sin.\,(N+p)},$$

whence

$$\sin.\,\Pi = \frac{\sin.\,P\,\cos.\,l}{\sin.\,\Delta}\,\sin.\,(H+\Pi).$$

Make $\frac{\sin.\,P\,\cos.\,l}{\sin.\,\Delta} = A$; then

sin. Π = A sin. (H + Π) = A (sin. H cos. Π + cos. H sin. Π);

whence

tan. Π = A (sin. H + cos. H. tan. Π),

and

tan. Π (1 — A cos. H) = A sin. H;

that is,

$$\tan.\,\Pi = \frac{A\,\sin.\,H}{1 - A\,\cos.\,H},$$

whence we have the following series,

$$\Pi = A\,\frac{\sin.\,H}{\sin.\,1''} + A^2\,\frac{\sin.\,2H}{\sin.\,2''} +, \&c.$$

PROBLEM XVI.—*To compute the parallax in declination.*

Make π = PB — PA (fig. 129) = the parallax in declination.

From the triangle ZPA we get

$$\cos.\,PZA = \frac{\cos.\,AP - \cos.\,PZ\,\cos.\,AZ}{\sin.\,PZ\,\sin.\,AZ},$$

and from ZPB

$$\cos.\,PZB = \frac{\cos.\,BP - \cos.\,PZ\,\cos.\,BZ}{\sin.\,PZ\,\sin.\,BZ};$$

therefore

$$\frac{\cos.\,AP - \cos.\,PZ\,\cos.\,AZ}{\sin.\,AZ} = \frac{\cos.\,BP - \cos.\,PZ\,\cos.\,BZ}{\sin.\,BZ},$$

that is (retaining the notation of last problem),

$$\frac{\cos.\,\Delta - \sin.\,l\,\cos.\,N}{\sin.\,N} = \frac{\cos.\,(\Delta+\pi) - \sin.\,l\,\cos.\,(N+p)}{\sin.\,(N+p)};$$

Practical Astronomy.

whence

$$\cos.\,(\Delta+\pi) = \frac{\cos.\,\Delta\,\sin.\,(N+p)}{\sin.\,N} - \frac{\sin.\,l\,[\cos.\,N\,\sin.\,(N+p) - \sin.\,N\,\cos.\,(N+p)]}{\sin.\,N}$$

$$= \frac{\cos.\,\Delta\,\sin.\,(N+p)}{\sin.\,N} - \frac{\sin.\,l\,\sin.\,p}{\sin.\,N},$$

$$= \frac{\cos.\,\Delta\,\sin.\,(N+p)}{\sin.\,N} - \frac{\sin.\,l\,\sin.\,P\,\sin.\,(N+p)}{\sin.\,N};$$

therefore

$$\cos.\,(\Delta+\pi) = \frac{\sin.\,(N+p)}{\sin.\,N}\,[\cos.\,\Delta - \sin.\,l\,\sin.\,P] \ldots (1)$$

Now, from the property of spherical triangles,

Sin. ZA : sin. PA : : sin. ZPA : sin. AZP,

therefore

$$\sin.\,AZP = \frac{\sin.\,PA\,\sin.\,ZPA}{\sin.\,ZA}.$$

For the same reason

$$\sin.\,BZP = \frac{\sin.\,PB\,\sin.\,ZPB}{\sin.\,ZB};$$

therefore

$$\frac{\sin.\,PA\,\sin.\,ZPA}{\sin.\,ZA} = \frac{\sin.\,PB\,\sin.\,ZPB}{\sin.\,ZB},$$

that is,

$$\frac{\sin.\,\Delta\,\sin.\,H}{\sin.\,N} = \frac{\sin.\,(\Delta+\pi)\,\sin.\,(H+\Pi)}{\sin.\,(N+p)},$$

whence

$$\frac{\sin.\,(N+p)}{\sin.\,N} = \frac{\sin.\,(\Delta+\pi)}{\sin.\,\Delta}\cdot\frac{\sin.\,(H+\Pi)}{\sin.\,H}.$$

By substituting this in equation (1) there results

$$\cos.\,(\Delta+\pi) = \frac{\sin.\,(\Delta+\pi)}{\sin.\,\Delta}\cdot\frac{\sin.\,(H+\Pi)}{\sin.\,H}\,[\cos.\,\Delta - \sin.\,l\,\sin.\,P],$$

whence

$$\cot.\,(\Delta+\pi) = \frac{\sin.\,(H+\Pi)}{\sin.\,H}\left\{\cot.\,\Delta - \frac{\sin.\,l\,\sin.\,P}{\sin.\,\Delta}\right\}.$$

Make $\frac{\sin.\,l\,\sin.\,P}{\sin.\,\Delta} = \cot.\,\alpha$, then

$$\cot.\,(\Delta+\pi) = \frac{\sin.\,(H+\Pi)}{\sin.\,H}\,(\cot.\,\Delta - \cot.\,\alpha),$$

that is,

$$\cot.\,(\Delta+\pi) = \frac{\sin.\,(H+\Pi)\,\sin.\,(\alpha-\Delta)}{\sin.\,H\,\sin.\,\alpha\,\sin.\,\Delta},$$

from which, as Δ is known, cot. (Δ + π) may be computed, and thence π. A more convenient formula, however, may be obtained by proceeding as follows. (See Delambre, *Abrégé d'Astronomie*, p. 154).

From the equation

$$\cot.\,(\Delta+\pi) = \frac{\sin.\,(H+\Pi)}{\sin.\,H}\left(\cot.\,\Delta - \frac{\sin.\,l\,\sin.\,P}{\sin.\,\Delta}\right)$$

we have

$$\cot.\,\Delta = \frac{\sin.\,H\,\cot.\,(\Delta+\pi)}{\sin.\,(H+\Pi)} + \frac{\sin.\,l\,\sin.\,P}{\sin.\,\Delta};$$

whence

$$\cot.\,\Delta - \cot.\,(\Delta+\pi) = \frac{\sin.\,H\,\cot.\,(\Delta+\pi)}{\sin.\,(H+\Pi)} - \cot.\,(\Delta+\pi) + \frac{\sin.\,l\,\sin.\,P}{\sin.\,\Delta};$$

but cot. Δ — cot. (Δ + π) =

Practical Astronomy.

$$\frac{\sin.(\Delta+\pi)\cos.\Delta-\cos.(\Delta+\pi)\sin.\Delta}{\sin.(\Delta+\pi)\sin.\Delta}=\frac{\sin.\pi}{\sin.(\Delta+\pi)\sin.\Delta};$$

therefore

$$\frac{\sin.\pi}{\sin.(\Delta+\pi)\sin.\Delta}=\frac{\sin.l\sin.P}{\sin.\Delta.}$$
$$-\frac{\cot.(\Delta+\pi)[\sin.(H+\Pi)-\sin.H]}{\sin.(H+\Pi)}.$$

Now, by the trigonometrical formulæ, the difference of the sines of two arcs is equal to twice the sine of half their difference multiplied by the cosine of half their sum, therefore

$$\sin.(H+\Pi)-\sin.H=2\sin.\tfrac{1}{2}\Pi\cos.(H+\tfrac{1}{2}\Pi),$$

whence

$$\frac{\sin.\pi}{\sin.(\Delta+\pi)\sin.\Delta}=\frac{\sin.l\sin.P}{\sin.\Delta}$$
$$-\frac{2\sin.\tfrac{1}{2}\Pi\cos.(H+\tfrac{1}{2}\Pi)\cot.(\Delta+\pi)}{\sin.(H+\Pi)};$$

and $\sin.\pi=\sin.l\sin.P\sin.(\Delta+\pi)$

$$-\frac{2\sin.\tfrac{1}{2}\Pi\sin.\Delta\cos.(H+\tfrac{1}{2}\Pi)\cos.(\Delta+\pi)}{\sin.(H+\Pi)},$$

or, since $2\sin.\tfrac{1}{2}\Pi=\frac{\sin.\Pi}{\cos.\frac{1}{2}\Pi}$,

$$\sin.\pi=\sin.l\sin.P\sin.(\Delta+\pi)$$
$$-\frac{\sin.\Pi\sin.\Delta\cos.(H+\frac{1}{2}\Pi)\cos.(\Delta+\pi)}{\cos.\frac{1}{2}\Pi\sin.(H+\Pi)}.$$

But it was shown in the last problem that

$$\sin.\Pi=\frac{\sin.P\cos.l}{\sin\Delta.}\sin.(H+\Pi),$$

whence

$$\frac{\sin.\Pi\sin.\Delta}{\sin.(H+\Pi)}=\sin.P.\cos.l;$$

consequently,

$$\sin.\pi=\sin.l\sin.P\sin.(\Delta+\pi)$$
$$-\frac{\sin.P\cos.l\cos.(H+\frac{1}{2}\Pi)\cos.(\Delta+\pi)}{\cos.\frac{1}{2}\Pi}.$$

Make $\tan.x=\frac{\cos.(H+\frac{1}{2}\Pi)\cot.l}{\cos.\frac{1}{2}\Pi}$; then, by substituting,

$$\sin.\pi=\sin.l\sin.P\,[\sin.(\Delta+\pi)-\tan.x\cos.(\Delta+\pi)],$$

or $\sin.\pi=$

$$\frac{\sin.l\sin.P}{\cos.x}[\sin.(\Delta+\pi)\cos.x-\cos.(\Delta+\pi)\sin.x],$$

$$\sin.\pi=\frac{\sin.l\sin.P}{\cos.x}\sin.(\Delta+\pi-x),$$

$\sin.\pi=$

$$\frac{\sin.l\sin.P}{\cos.x}[\sin.(\Delta-x)\cos.\pi+\cos.(\Delta-x)\sin.\pi];$$

whence,

$\tan.\pi=$

$$\frac{\sin.l\sin.P}{\cos.x}[\sin.(\Delta-x)+\cos.(\Delta-x)\tan.\pi];$$

therefore (making $\frac{\sin.l\sin.P}{\cos.x}=B$),

$$\tan.\pi=\frac{B\sin.(\Delta-x)}{1-B\cos.(\Delta-x)},\text{ consequently}$$

$$\pi=B\frac{\sin.(\Delta-x)}{\sin.1''}+B^2\frac{\sin.2(\Delta-x)}{\sin.2''}$$
$$+B^3\frac{\sin.3(\Delta-x)}{\sin.3''}+,\&c.$$

PROBLEM XVII.—*To compute the altitude and longitude of the nonagesimal.*

The nonagesimal is the point of the ecliptic where that circle intersects the vertical plane passing through its pole. It is consequently the highest point of the ecliptic above the horizon, or 90° from the horizon measured on the ecliptic. Practical Astronomy.

Let HH′ (fig. 129) be the horizon, EO the ecliptic, EQ the equator, Z the zenith, P the pole of the equator, and P′ the pole of the ecliptic. The great circle passing through P′ and P intersects EO and EQ at right angles in C and D, whence EC = ED = 90° = MQ, and therefore EM = DQ. In like manner PD = 90° = P′C, consequently P′P = CD the obliquity of the ecliptic.

The great circle PZNI which passes through the pole of the ecliptic and the zenith is a circle of latitude and also a vertical circle; hence the angles at N and I are right angles, and O is the pole of PZNI; consequently OI = ON = 90°. Now since ON = 90°, the point N is the nonagesimal, and its altitude IN = 90° − ZN = ZP′ = the complement of the altitude of the pole of the ecliptic, or the co-latitude of the zenith. In like manner its longitude EN = 90° − NC = 90° − ZP′P. Now in order to compute ZP′ and the angle ZP′P, we have given, in the triangle ZPP′, the side ZP = the co-latitude, PP′ = the obliquity, and also the angle ZPP′, for ZPP′ = 180° − ZPD = 180° − MD = 180° − (ED − EM) = 180° − 90° + EM = 90° + EM, and EM (which is the right ascension of the zenith, or as it is technically called, the right ascension of the mid-heaven) is given, being equal to the sidereal time of observation converted into degrees.

Let R = EM the right ascension of the zenith, λ = PZ the co-latitude of the place (reduced by problem XIII.), ω = PP′ the obliquity of the ecliptic, K = P′Z the co-latitude of the zenith or altitude of the nonagesimal, N = 90° − ZP′P the longitude of the nonagesimal.

By the trigonometrical formulæ,

$$\cos.K=\cos.\lambda\cos.\omega+\sin.\lambda\sin.\omega\cos.(90°+R)$$
$$=\cos.\lambda\cos.\omega+\sin.\lambda\sin.\omega\sin.R.$$

Assume $\tan.\varphi=\tan.\lambda\sin.R$, then, by substituting and reducing, we obtain

$$\cos.K=\frac{\cos.\lambda}{\cos.\varphi}\cos.(\omega+\varphi).$$

To find the longitude L, we have

$$\tan.N=\frac{\cot.\lambda\sin.\omega}{\sin.(90°+R)}-\cot.(90+R)\cos.\omega$$
$$=\frac{\cot.\lambda\sin.\omega}{\cos.R}+\tan.R\cos.\omega,$$

But $\tan.\lambda=\frac{\tan.\varphi}{\sin.R}$, whence $\cot.\lambda=\frac{\sin.R}{\tan.\varphi}$,

whence, by substituting,

$$\tan.N.=\tan.R\left(\frac{\sin.\omega}{\tan.\varphi}+\cos.\omega\right),$$

and on reducing,

$$\tan.N=\frac{\tan.R}{\sin.\varphi}\sin.(\omega+\varphi),$$

PROBLEM XVIII.—*To compute the parallax in longitude and latitude.*

Let A (fig. 129) be the place of the star situated on the vertical ZAR; E*a* is its longitude, and P′A the complement of its latitude, or its distance from the pole of the ecliptic. Suppose that, through the effects of parallax, it is depressed from A to B; its longitude then becomes E*b*, and its distance from the pole of the ecliptic P′B, so that *ab* is the variation in longitude, and P′B − PA the variation in latitude, which it is required to compute. Now it is evident that these quantities will be given in terms of the different parts of the triangle AP′B, exactly in the same manner as the parallax in right ascension and declination has been found from the triangle APB

Practical Astronomy.

(fig. 128). The angle ZPA, which was before denoted by H, now becomes ZP'A = Na = Ea — EN = longitude of the star — longitude of the nonagesimal, and ZPB becomes ZP'B = Nb = Na + ab. Retaining, therefore, the notation employed in the three last problems, and making L = Ea the longitude of the star, Δ' = PA its distance from the pole of the ecliptic, k = ZP' = 90° — K, Π' = ab its parallax in longitude, π' = P'B — P'A its parallax in latitude, we shall have Π' and π' from the same formulæ as Π and π in Problems XV. and XVI., by changing l into k, H into L — N, and Δ into Δ'. Hence (Problem XV.)

$$\text{sin. } \Pi' = \frac{\text{sin. P cos. } k}{\text{sin. } \Delta}, \text{ sin. (L — N + } \Pi'),$$

and by putting $C = \frac{\text{sin. P cos. } k}{\text{sin. } \Delta'}$, we deduce

$$\text{tan. } \Pi' = \frac{C \text{ sin. (L — N)}}{1 - C \text{ cos. (L — N)}} \text{ and}$$

$$\Pi' = \text{sin. } C \frac{\text{sin. (L — N)}}{\text{sin. } 1''} + C^2 \frac{\text{sin. } 2\text{ (L — N)}}{\text{sin. } 2''} +, \text{ \&c.}$$

In like manner the formula for the parallax in declination given in Problem XVI., viz.

$$\text{cot. } (\Delta + \pi) = \frac{\text{sin. (H + } \Pi)}{\text{sin. H}} \left[\text{cot. } \Delta - \frac{\text{sin. } l \text{ sin. P}}{\text{sin. } \Delta} \right]$$

becomes

$$\text{cot. } (\Delta' + \pi') = \frac{\text{sin. (L — N + } \Pi')}{\text{sin. (L — N)}} \left[\text{cot. } \Delta' - \frac{\text{sin. } k \text{ sin. P}}{\text{sin. } \Delta'} \right];$$

from which, by proceeding in the same manner as in Problem XVI., and making

$$\text{tan. } x' = \frac{\text{cos. (L — N + } \frac{1}{2} \Pi') \text{ cot. } k}{\text{cos. } \frac{1}{2} \Pi'}$$

we deduce tan. π'

$$= \frac{\text{sin. } k \text{ sin. P}}{\text{cos. } x'} \left[\text{sin. } (\Delta' - x') + \text{cos. } (\Delta' - x') \text{ tan. } \pi' \right]$$

whence, on making $\frac{\text{sin. } k \text{ sin. P}}{\text{cos. } x'} = D$,

$$\text{tan. } \pi' = \frac{D \text{ sin. } (\Delta - x')}{1 - D \text{ cos. } (\Delta' - x')},$$

consequently

$$\pi' = D \frac{\text{sin. } (\Delta' - x')}{\text{sin. } 1''} + D^2 \frac{\text{sin. } 2\ (\Delta' - x')}{\text{sin. } 2''} +, \text{ \&c.}$$

PROBLEM XIX.—*Given the apparent altitudes of the moon and the sun, or a star, and the apparent distance between them, to find the true distance.*

This is a problem of great importance in Practical Astronomy, because the observed distance between the moon and the sun or a star is the surest means the navigator has to determine his longitude.

To obtain the apparent distance and altitudes, it is convenient to have three observers: one, the most expert, takes the apparent distance of the limb of the moon from that of the sun, or from the star; another observes the moon's altitude at the moment of the observation of the distance; and a third takes the star's altitude. For greater accuracy, these simultaneous operations ought to be repeated several times, and a fourth assistant may, by a good watch, note the intervals of time between them. A mean of the whole will then be obtained, and the corresponding time by the watch, by which the true time at that place will be nearly known. If there be only one observer, he must take the altitudes immediately before and after the distance, and endeavour to allow for the change of altitude during the time between the observations.

The observed distance between the limbs of the moon and sun must be increased by their semidiameters to obtain the distance of their centres. If the distance from a star is taken, because its diameter is insensible, the distance is to be increased by the moon's semidiameter only. Practical Astronomy

The observed altitudes thus found are affected by parallax and refraction. The moon's horizontal parallax is given in the *Nautical Almanac*: from this the parallax at the time of observation may be found by Prob. XIV., but the navigator avails himself of aid from *The Requisite Tables*, which shorten the process of calculation. The sun's parallax is almost insensible, but it may be taken into account; that of a star is accounted nothing. The altitudes are diminished by the parallaxes, but they are increased by refraction. The sun's altitude is more increased by the latter than diminished by the former; but the reverse happens with the moon. At sea the altitudes must be also corrected for the *dip of the horizon* (that is, for the height of the observer above the surface of the sea), and the refraction for the height of the thermometer.

Supposing all this done, let S and M be the true places of the sun or star and moon (fig. 130), Z the zenith; because parallax and refraction take place only in vertical circles, the apparent place of the sun, s, will be in the vertical ZS above S, and that of the moon, m, in ZM below M. The apparent distance will be sm.

Let A = 90° — ZM be the moon's true altitude; a = 90° — ZS the star's true altitude; H = 90° — Zm the moon's apparent altitude; h = 90° — Zs the star's apparent altitude; D = SM the true, and d = sm the apparent distance.

By spherical trigonometry, in the triangles SZM, sZm,

$$\text{os. SZM} \begin{cases} = \dfrac{\text{cos. D — sin. A sin. } a}{\text{cos. A cos. } a}, \\ = \dfrac{\text{cos. } d \text{ — sin. H sin. } h}{\text{cos. H cos. } h}. \end{cases}$$

From these equal values of cos. SZM we find

$$\text{cos D} = (\text{cos. } d - \text{sin. H sin. } h) \frac{\text{cos. A cos. } a}{\text{cos. H cos. } h} + \text{sin. A sin. } a$$

$$= [\text{cos. } d + \text{cos. (H + } h) - \text{cos. H cos. } h] \frac{\text{cos. A cos. } a}{\text{cos. H cos. } h} + \text{sin. A sin. } a$$

$$= 2 \text{ cos. } \tfrac{1}{2} \text{ (H + } h + d) \text{ cos. } \tfrac{1}{2} \text{ (H + } h - d) \frac{\text{cos. A cos. } a}{\text{cos. H cos. } h} - (\text{cos. A cos. } a - \text{sin. A sin. } a).$$

But the last term = cos. (A + a); subtract now both sides from 1; then, observing that by the calculus of sines (see ALGEBRA)

$$1 - \text{cos. D} = 2 \text{ sin.}^2 \tfrac{1}{2} \text{ D},$$
$$1 + \text{cos. (A + } a) = 2 \text{ cos.}^2 \tfrac{1}{2} \text{ (A + } a),$$

we have, after dividing by 2, and putting

$$F = \frac{\text{cos. A cos. } a}{\text{cos. H cos. } h},$$

$$\text{sin.}^2 \tfrac{1}{2} \text{ D} = \text{cos.}^2 \tfrac{1}{2} \text{ (A + } a) - \text{cos. } \tfrac{1}{2} \text{ (H + } h + d) \text{ cos. } \tfrac{1}{2} \text{ (H + } h - d) \times F$$

$$= \text{cos.}^2 \tfrac{1}{2} \text{(A + } a) \left[1 - \frac{\text{cos. } \frac{1}{2} \text{(H + } h + d) \text{cos. } \frac{1}{2} \text{(H + } h - d)}{\text{cos.}^2 \frac{1}{2} \text{ (A + } a)} \times F \right].$$

Let θ be such an angle that

$$\text{sin.}^2 \theta = \frac{\text{cos. } \frac{1}{2} \text{ (H + } h + d) \text{ cos. } \frac{1}{2} \text{ (H + } h - d) \text{ cos. A cos. } a}{\text{cos.}^2 \frac{1}{2} \text{ (A + } a) \text{ cos. H cos. } h};$$

and in this expression the value of F is put instead of it, then we have

$$\text{sin.}^2 \tfrac{1}{2} \text{ D} = \text{cos.}^2 \tfrac{1}{2} \text{ (A + } a) \text{ cos.}^2 \theta;$$
$$\text{and sin. } \tfrac{1}{2} \text{ D} = \text{cos. } \tfrac{1}{2} \text{ (A + } a) \text{ cos. } \theta.$$

The value of cos. D in the first formula may serve to determine D, but not conveniently; by the various steps of the analytic process it is transformed into another, viz.

the last, which gives sin. $\frac{1}{2}$ D, and consequently D readily by logarithmic calculation.

The final result is the rule found by Borda: as a practical rule it is very convenient, because no attention is necessary to the signs of the trigonometrical quantities. On this account it is well adapted to seamen.

PROBLEM XX.—*To find the longitude of a ship at sea by an observation of the distance of the moon from the sun or a star.*

From the observed distance, the true distance as it would appear if it could be seen from the earth's centre, may be found by the last problem: Now by the *Nautical Almanac* this is given for every third hour, Greenwich time, therefore, by an easy calculation, the time at which the observation was made, as it would be given by a watch showing Greenwich time, may be obtained. But the time of observation as reckoned at the ship may be found from the ship's latitude, the moon's or star's zenith distances (found by the observation), and their polar distances as given by the Almanac. Therefore the difference between the time of the observation as estimated at the ship and the corresponding Greenwich time becomes known: This difference is the *ship's longitude.*

Example. At sea, June 5, 1793, about an hour and a half after noon, in 10° 46′ 50″ south latitude, and 149° longitude, by account, by means of a set of lunar observations made at a height of about 20 feet above the surface of the sea, it was found that

Distance of nearest limbs of ☉ and ☽ ...83° 26′ 46″
Altitude of lowest limb of ☉.....48 16 10
Altitude of upper limb of ☽.....27 53 30.

Hence the longitude of the ship is required.

Reduction of the apparent to the true altitude.

Dist. of nearest limbs of ☉ and ☽	83°	26′	46″

True alt. of moon's centre (A).....	28°	20′	48″

Reduction of the apparent to the true distance by Prob. XIX.

	d	83°	57′	33″	
	h	48	27	32	ar. com. cos. ·1783835
	H	27	34	5	ar. com. cos. ·0523390
	sum	159°	59′	10″	
	$\frac{1}{2}$ sum	79	59	35	cos. 9·2399686
$d - \frac{1}{2}$	sum	3	57	58	cos. 9·9989587
	a	48	26	49	cos. 9·8217187
	A	28	20	48	cos. 9·9445275
A + a =		76°	47′	37″	39·2358960

$\frac{1}{2}$(A + a) =	38	23	48		2 log. cos. 19·7883324
					2)19·4475636
θ =	31	57	33		cos. θ 9·7237818
					sin. 9·9285875
$\frac{1}{2}$(A + a) =	38	23	48		cos. 9·8941662
$\frac{1}{2}$ D =	41	40	27⅔		sin. 9·8227537
D =	83	20	55	nearly.	

Computation of time at Greenwich.

By Nautical Almanac for 1793

Dist. ☽ from ☉ at 15 hours.....	83°	6′	1″
at 18.....	84	28	26
Increase of dist. in 3 hours =	1°	22′	25″
D..... =	83°	20′	55″
Dist. ☽ from ☉ at 15 hours....	83	6	1
	0°	14′	54″

Hence it appears that in 3 hours the distance of the moon from the sun was increased by 1° 22′ 25″ = 4595″, and that between the time of making the observation, and the 15th hour, Greenwich time, the increase of distance was 0° 14′ 54″ = 894.″ Now for small intervals the distances will increase nearly as the times, therefore we have

4945″ : 894″ : : 3h. : 0h. · 5425 = 32m. 33s.

Thus it appears that the observation must have been made 32 minutes 33 seconds after the 15th hour, Greenwich time.

We have yet to find the *correct* time of the observation as estimated at the ship. To determine this, we know the sun's altitude 48° 26′ 49″, and the sun's declination, which is given in the Almanac for Greenwich, noon; and from this the declination at the time of the observation is found by making allowance for the difference of longitude and the hour from noon at the ship, both known nearly. The declination thus found is 23° 22′ 48″ north. The ship's latitude, 10° 16′ 40″, is also known. Hence to find the hour angle by Problem IV. we have

λ the colat. = 79° 43′ 20″,
Δ the pol. dist. = 113 22 48,
z the zenith dist. = 41 33 11.

To find P the hour angle, the computation (see formula of Prob. IV.) may stand thus:—

sin. $\frac{1}{2}$ (z + λ — Δ)	3°	56′	51″		8·8378559
sin. $\frac{1}{2}$ (z — λ + Δ)	37	36	19		9·7854851
sin. $\frac{1}{2}$ (λ + Δ + z)	117	19	39	ar. comp.	0·0513929
sin. $\frac{1}{2}$ (λ + Δ — z)	75	46	28	ar. comp.	0·0135256
					2)18·6882595
tan. ($\frac{1}{2}$ P =	12°	27′	17½″)		9·3441297
P =	24°	54′	35″ =		1h 39m 38s·3
time at Greenwich =					15 32 33·0
Long. from Greenwich *westward*					13h 52m 54s·7
Therefore, longitude east of Greenwich is					10h 7m 4s·3

We have put down the result to seconds, as it comes out by the calculation; but such accuracy is not attainable in nautical practice. Delambre says, "even with the best instruments, the most skilful navigators find anomalies for which they cannot account. The lunar tables are in a state of continual improvement, yet we cannot be sure that there is not an error of 20″ in a distance, which will produce an error of 40″ of time. To this possible error of theory must be joined that of the observation, which may be still greater. The error of the time may therefore amount to 80″, which is equivalent to 20′, or $\frac{1}{3}$d of a degree. This should be the *maximum* of the error; and, in general, this degree of accuracy is sufficient. Indeed a greater accuracy than $\frac{1}{3}$d or $\frac{1}{4}$th of a degree may sometimes be obtained, but still it is uncertain.

CHAP. II.

CALCULATION OF NEW AND FULL MOON, AND ECLIPSES.

	—	XI.s.		+	—	X.s.		+	—	IX.s.		+	—	VIII.s.		+	—	VII.s.		+	—	VI.s.		+	

Multiply the Secular Variations by the number of years between the given time and the year 1801, and divide the product by 100. If the given time be before 1801, change the sign of the Secular Variation.

		— XI.s.		+		— X.s.		+		— IX.s.		+		— VIII.s.		+		— VII.s.		+		— VI.s.		+	

Multiply the secular variations by the number of years between the given time and the year 1801, and divide the product by 100. If the time is before 1801, change the sign of the secular variation.

TABLE XVII.

For the Moon's Latitude and Inclination of her relative Orbit to the Ecliptic in Eclipses.

Argument. Moon's True distance from Ascending Node.

Multiply the secular variation by the number of years between the given time and the year 1801, and divide the product by 100. If the given time be before 1801, change the sign of the secular variation.

SECT. II.—*Application of the Tables, and Projection of Eclipses.*

PROBLEM I.—*To calculate the time of true new or full moon for any period within the limits of the nineteenth century.*

Precept 1. Write out the time of mean new moon in January for the proposed year from Table I., together with the mean anomalies of the moon and sun, and the moon's mean distance from her ascending node, applying to each of these quantities the secular equation found by its side by addition or subtraction, according as it has the sign + or —. If you want the time of full moon in January, add the half-lunation at the foot of Table IV., with its anomalies, &c. to the former numbers if the new moon falls before the 15th of January; but if it falls after, subtract the half-lunation, with the anomalies, &c. belonging to it, from the former numbers, and write down the respective sums or remainders.

2. In these additions or subtractions, observe that 60 seconds make a minute, 60 minutes make a degree, 30 degrees make a sign, and 12 signs make a circle. When you exceed 12 signs in addition, reject 12, and set down the remainder. When the number of signs to be subtracted is greater than the number you subtract from, add 12 signs to the lesser number, and then you will have a remainder to set down. In the tables, signs are marked S, degrees D, minutes M, and seconds S.

3. When the required new or full moon is in any given month after January, write out from Table IV. such one of the mean lunations, with the anomalies, &c. as, added to the time of mean new or full moon in January, will make the mean new or full moon to fall within the given month, setting them below the number taken out for January.

4. Add all these together, and in leap-years (which in Table I. have the letter B annexed to them) subtract one day from the time of mean new or full moon when it happens after 28th February. You will then have the time of the required mean new or full moon, with the mean anomalies, and the moon's mean distance from the ascending node, which are the arguments for finding the proper equations.

5. With the signs and degrees of the moon's mean anomaly enter Table V., and therewith take out the first equation for reducing the mean syzigy to the true; taking care to make proportions in the table for the odd minutes and seconds of anomaly, as the table gives the equation only to whole degrees.

Observe in this and every other case of finding equations, that, if the signs are at the head of the table, their degrees are at the left hand, and are reckoned downwards; the equation being in the body of the table under or over the signs in a collateral line with the degrees. The signs + and — at the head or foot of the tables where the signs are found, show whether the equation is to be added to the time of mean new or full moon, or to be subtracted from it.

6. With the signs and degrees of the sun's mean anomaly enter Table VI. and take out the second equation for reducing the time of mean to that of new or full moon, with a proportional part of its secular variation in the column adjoining, corresponding to the number of years elapsed since 1801, the whole variation being adapted for a period of 100 years.

7. Add together the mean anomalies of the sun and moon, and with the sum enter Table VII. and take out the third equation. For this and the following equations it will be sufficient to compute the arguments to minutes, neglecting the seconds.

8. Subtract the sun's mean anomaly from the moon's mean anomaly, and with the remainder enter Table VIII. and take out the fourth equation.

9. Subtract the moon's mean anomaly from twice the moon's distance from the ascending node, and with the remainder enter Table IX. and take out the fifth equation.

10. The moon's mean distance from the ascending node is the argument of Table X., with which take out the sixth equation.

11. To twice the moon's mean anomaly add the sun's mean anomaly, and with the sum enter Table XI. and take out the seventh equation.

12. From twice the moon's mean anomaly subtract the sun's mean anomaly, and with the remainder enter Table XII. and take out the eighth equation.

13. These are all the equations for reducing the time of mean new moon to the time of true new moon; but for full moon other two equations are required, the argument for equation ninth being the moon's mean anomaly, which equation is exhibited in Table XIII.; and the argument of the tenth equation being the sun's mean anomaly, the equation being exhibited in Table XIV.

14. Add together the equations which have the sign of addition, and also those which have the sign of subtraction, and subtract the lesser sum from the greater, giving to the remainder the sign of the greater; and add or subtract the remainder, according as its sign denotes, to or from the time of mean new or full moon, and you have the time of true new or full moon required.

These tables are adapted to the meridian of Greenwich observatory; and for any other place, its longitude in time is to be added to or subtracted from the time given by the tables, according as it is to the east or west of Greenwich, and the time as reckoned at the given place is obtained. The tables begin the day at noon, and reckon forward from thence to the noon following. Thus January the 31st, at 22 hours 30 minutes 25 seconds of tabular time, is February 1st (in common reckoning), at 30 minutes 25 seconds after 10 o'clock in the morning. It is to be further observed, that the time obtained from the tables is mean time, or that shown by a well-regulated clock or watch. But to make it agree with solar or apparent time, or that given by a sun-dial, which is necessary in the computation of solar eclipses, you must apply the equation of time contained in Table XXVIII. as afterwards directed.

The method of calculating the time of any new or full moon, without the limits of the nineteenth century, will be shown farther on; and a few examples compared with the precepts will make the whole work plain.

EXAMPLE I.

Required the Time of True New Moon in May 1836 at Edinburgh, long. 0 hours 12 minutes 44 seconds west of Greenwich.

PROBLEM II.—*To calculate the time of new and full moon in a given year and month of any particular century between the Christian era and the nineteenth century.*

Note.—Prior to the sixteenth century the times are supposed to be reckoned according to the Julian calendar, or old style. Between it and the nineteenth century they may be reckoned according to either the Julian or Gregorian calendar, or old or new style.

Practical Astronomy.

Precept 1. Find a year of the same number in the nineteenth century, with that of the year in the century proposed, and take out the time of mean new moon in January for that year, with the mean anomalies, and the moon's mean distance from the node at that time, as already taught, neglecting the secular equations contained in Table I.

Precept 2. Take from Table II. as many complete centuries of years having the sign — prefixed, and titled either old style or new style, according to the given date, as, when subtracted from the above said year in the nineteeth century, will answer to the given year, and take out the time of mean new moon and its anomalies, &c. belonging to the said centuries, and add them to those for the year in the nineteenth century, and the sums, after applying to them the secular equations taken from Table III., making proportions for the odd years, will be the times and anomalies, &c. of mean new moon in January or February, according as the time is less or more than 31 days, in the given year of the century proposed. Then work in all respects for the time of true new or full moon, as shown in the above precepts and examples.

EXAMPLE III.

Required the True Time of New Moon in July 1339, Old Style.

PROBLEM III.—*To calculate the true time of new or full moon in any given year and month before the Christian era.*

Precept 1. Find a year in the nineteenth century which, being added to the given number of years before Christ diminished by one, shall make a number of complete centuries.

2. Find this number of centuries in Table II. and add the time and anomalies belonging to it to those of the above-found year of the nineteenth century, applying the secular equations for the given year in Table III., and the sums will denote the time and anomalies, &c. of mean new moon in January or February of the given year before Christ. Then for the true time of new or full moon proceed as above taught, for any year between the Christian era and the nineteenth century, observing that the given year before Christ is or is not leap-year, according as the above-mentioned year in the nineteenth century is leap-year or not.

PROBLEM IV.—*To calculate the time of true new or full moon, according to the Gregorian calendar or new style, in any given year or month of the 20th or 21st century.*

Precept 1. Find a year of the same number in the nineteenth century with that of the year proposed, and take out the mean time and anomalies, &c. of new moon for that year in Table I., omitting the secular equations.

2. Take so many years from Table II. having the sign + prefixed, as, when added to the above-mentioned year in the nineteenth century, will answer to the given year in which the new or full moon is required; and take out the time of new moon, with its anomalies, for these complete centuries.

3. Add these together, and to the sum apply the secular equations for the given year found in Table III., then work in all respects as above shown.

PROBLEM V.—*To find the true anomalies of the sun and moon, and the moon's true distance from the ascending node at the true time of new or full moon.*

With the sum of equations already found for reducing the time of mean new or full moon to that of the true, enter Table XV., and take therefrom the sun's mean motion from the moon's perigee, the change of the sun's mean anomaly, and the sun's mean motion from the ascending node, and apply these quantities to the mean anomalies and mean distance from the node at the time of mean new or full moon by addition or subtraction, according as the sum of the equations has the sign + or —. Then with the sun's corrected mean anomaly as argument, take from Table XVI. the equation of the sun's centre, correcting it for the secular variation as directed at the bottom of the table, and add or subtract the same to or from the corrected mean anomalies and mean distance from the node, and there will be obtained the true anomalies of the sun and moon, and the moon's true distance from the ascending node at the time of true new moon or full moon.

EXAMPLE VI.

Required the True Anomalies of the Sun and Moon, and the Moon's True Distance from the Ascending Node at the time of True New Moon in 1836.

The Sum of Equations is — 2h. 24m. 2s.

	At True New Moon.											

Elements for the Projection of Solar Eclipses.

When at the time of true new moon the moon's true distance from the ascending node is between 11s 11° 50′ and 0s 18° 10′, or 5s 11° 50′ and 6s 18° 10′, there may at that time be an eclipse of the sun to some place on the earth's surface; but if it is beyond those limits there can be no eclipse. At the new moon in May 1836, the moon's distance from the node being within the limits, there may be an eclipse of the sun at that time.

It being ascertained that there may be an eclipse, the elements for predicting it are to be obtained as explained in the following example of the solar eclipse in May 1836, which is to be predicted, as it will happen at Edinburgh, in latitude 55° 57′ N.

1. *The moon's latitude at the true time of new moon.* The moon's true distance from the ascending node at the time of true new moon is the argument of Table XVII.; the moon's true anomaly *minus* her true distance from the ascending node is the argument of Table XVIII.; this argument *plus* the moon's true anomaly is the argument of Table XIX.; the moon's true anomaly *plus* her true distance from the ascending node is the argument of Table XX.; the sun's true anomaly *plus* the moon's true distance from the ascending node is the argument of Table XXI.; and the sun's true anomaly *minus* the moon's true distance from the ascending node is the argument of Table XXII. With these arguments enter the respective tables, and take out the proper quantities, and add together such as have the sign +, and also such as have the sign —, and the difference of the two sums is the moon's latitude required, north if the greater sum has the sign +, south if it has —.

Practical Astronomy.

Example.

The Moon's Latitude at the time of true New Moon in May 1836.

	s.	d.	m.	s.	+ d.	m.	s.	— s.
Arg. Table XVII.	0	4	53	32	0	25	47	
.... XVIII.	4	24	31					7
.... XIX.	9	23	56					23
.... XX.	5	4	18				7	
.... XXI.	4	19	30				13	
.... XXII.	4	9	42				25	
					+ 0	26	32	— 30
							— 30	
Moon's latitude north.....					+ 0	26	2	

II. *The inclination of the moon's relative orbit to the ecliptic* is found in Table XVII., with the moon's true distance from the ascending node for argument. In the present instance the inclination is 5° 43', left, signifying that the axis of the moon's orbit is to the left hand of the northern axis of the ecliptic.

III. *The semidiameter of the earth's disk* is equal to the difference of the moon's horizontal parallax corrected for the latitude of the given place, and the sun's horizontal parallax, which may always be assumed equal to nine seconds. The moon's equatorial horizontal parallax is found in Table XXIII., with her true anomaly for argument; and the correction to be subtracted therefrom is obtained in Table XXIV., with the latitude of the place and equatorial parallax as joint arguments. Thus, in the present instance, the moon's equatorial horizontal parallax is.....54′ 26″
The correction to be subtracted..... 8″

Leaving for reduced horizontal parallax.....54′ 18″
which being again diminished by the sun's horizontal parallax, there remains 54′ 9″ for the semidiameter of the earth's disk.

IV. *The sun's semidiameter* is also obtained in Table XXII., with his mean anomaly as argument. We have, therefore, sun's semidiameter 15′ 51″.

V. *The moon's semidiameter* is likewise obtained in Table XXII., with her true anomaly as argument. Hence, moon's semidiameter = 14′ 50″. Practical Astronomy

VI. *The moon's horary motion from the sun* is equal to the difference of the sun's and moon's horary motions; both of which are found in Table XXII., with the sun's mean anomaly and the moon's true anomaly as arguments. Hence

Sun's horary motion ..... 2′ 25″
Moon's horary motion .....30′ 9″
Moon's horary motion from the sun.....27′ 44″

VII. *The sun's true longitude at the true time of new moon* is equal to the longitude of the sun's perigee added to his true anomaly. The longitude of the perigee is obtained by taking from Table XXV. the epoch of the first year of the century to which the given year belongs, and adding thereto the motion in Table XXVI. answering to the remaining number of years, months, and days, but subtracting therefrom a proportional part of the secular variation of the precession of the equinoxes found in Table XXV. opposite the first year of the given century, corresponding to the remaining number of years.

Example.

	Longitude of Perigee. s.	d.	m.	s.
1801.....	9	9	30	5
30 years.....			30	57
5 do.....			5	9
May.....				20
15 days.....				2
Longitude of perigee...	9	10	6	33
Sun's true anomaly.....	4	14	36	0
Sun's true longitude.....	1	24	42	33

VIII. *The sun's declination* is found in Table XXVII., with the sun's true longitude for argument, and is to be corrected by the secular variation given in the same table, as directed at the bottom. The declination is north or south according as it bears the sign + or —, and, in the table, is given to tenths of a minute.

Example.

	s.	d.	m.	s.		d.	m.
Sun's true longitude.....	1	24	42	33	Declination	+18	58·0
Secular variation		$\frac{-0{\cdot}6 \times 35}{100}$			=		−0·2
Sun's declination, north.....						+18	57·8

IX. *The apparent time of new moon.* The mean time of new moon, already found and reduced to the place for which the prediction is to be made, is to be converted into apparent time, by applying thereto, according to the sign, the equation of time found in Table XXVIII., with the sun's true longitude for argument, and corrected for the secular variation given in the same table, as in the following example:

Example.

Mean time of true new moon at Edinburgh on May 15, 1836..... H. 1 M. 51 S. 11

	s.	d.	m.		m.	s.	
Sun's true longitude	1	24	43	Equation of time,	+3	59	
Secular variation.....	$\frac{-10^s \times 35}{100}$			=	−3		.....+3 56

Apparent time of true new moon..... 1 55 7

X. *The reduced latitude of the given place* is obtained by subtracting from the true latitude the correction in the last column of Table XXIV. answering to the latitude. In this particular case,

Edinburgh being in north latitude.....55° 57′
The correction is..... 10′·8

Reduced latitude.....55° 46′·2

Practical Astronomy

To Project an Eclipse of the Sun geometrically.

Take from a scale of any convenient length as many equal parts as the semidiameter of the earth's disk contains minutes of a degree, which for Edinburgh at the time of the eclipse in May 1836 is 54′ 10″, or 54$\frac{1}{6}$′. Then with this quantity as a radius describe the semicircle AHB upon the centre C (Plate XCI. fig. 136); which semicircle shall represent the northern half of the earth's enlightened disk as seen from the sun. If the given place were in south latitude, the southern half of the earth's disk must be represented.

Upon the centre C raise the straight line CH perpendicular to the diameter ACB; so ACB shall be a part of the ecliptic, and CH its axis.

Being provided with a sector,[1] open it to the radius CA in the line of chords; and taking from thence the chord of the sun's greatest declination or the obliquity of the ecliptic for the given time (in the present instance 23° 28′) in your compasses, set it off both ways from H to *g*, and to *h* in the periphery of the semi-disk; and draw the straight line *g* V *h*, in which the north pole of the disk will be always found.

When the sun's longitude is between O^s. and VI^s. the north pole of the earth is enlightened by the sun; but whilst the sun is in the other six signs, the south pole is enlightened and the north pole is in the dark.

And when the sun's longitude is between IX^s. and III^s. the northern half of the earth's axis C XII. P lies to the right hand of the axis of the ecliptic as seen from the sun; and to the left hand while the sun is in the other six signs. It is evident that a contrary rule prevails with regard to the southern half of the earth's axis.

Open the sector till the radius of the sines be equal to the length of V^h, and take the sine of the difference of the sun's longitude from III.^{s} or IX.^{s}, whichever it is nearest (in the present instance 35° 17′), in your compasses from the line of the sines, and set off that distance from V to P in the line *g*V*h*, because the northern half of the earth's axis lies to the right hand of the axis of the ecliptic in this case; and draw the straight line C XII. P for the earth's axis, of which P is the north pole. If the earth's axis had lain to the left hand of the axis of the ecliptic, the distance VP would have been set off from V towards *g*.

To draw the parallel of latitude of the given place, Edinburgh, or the path of that place, on the earth's enlightened disk, as seen from the sun from sunrise till sunset, take the following method:—

Find the sum and difference of the reduced latitude 55° 46′ and the sun's declination 18° 58′, which are 74° 44′ and 36° 48′. Take these arcs from the line of sines on the sector, CA being radius, and set them off from C to the two points, each marked XII. in the line of the earth's axis.

Bisect XII. — XII., and through the point K draw the line VI. K VI. perpendicular to the axis. Then, making CA or CB the radius of a line of sines on the sector, take the co-latitude of Edinburgh, 34° 14′, from the sines in your compasses, and set it both ways from K to VI. and VI. These hours will be just in the edge of the disk at the equinoxes; but at no other time in the whole year.

With the extent K VI. taken into your compasses, set one foot in K as a centre, and with the other foot describe the semicircle VI., 7, 8, 9, 10, &c., and divide it into 12 equal parts. Then from these points of division draw lines parallel to the earth's axis C XII. P.

With the extent K XII. as a radius, describe the quadrantal arc XII. *f*, and divide it into six equal parts, as XII. *a*, *ab*, *bc*, *cd*, *de*, and *ef*, and through the division points, *a*, *b*, *c*, *d*, *e*, draw the lines VII. *e* V., VIII. *d* IV., IX. *c* III., X. *b* II., and XI. *a* I., all parallel to VI. K VI., and meeting the former lines in the points VII., VIII., IX., X., XI., V., IV., III., II., and I.; which points shall mark the several situations of Edinburgh on the earth's disk, at these hours respectively as seen from the sun; and the elliptic curve VI., VII., VIII., &c. being drawn through these points, shall represent the parallel of latitude, or path of Edinburgh, as seen from the sun from six in the morning to six in the afternoon. On continuing the lines VII. *p*, VIII. *o*, &c. IV. *u*, V. *x*, &c. on the other side of VI. K VI., and setting off *p* V. equal to VII. *p*, *o* IV. equal to VIII. *o*, &c., and continuing the elliptic curve through the points V. IV. &c., VII. VIII. &c., the path of Edinburgh, as seen from the sun before six in the morning and after six in the afternoon, will be had; but it is needless to draw the curve farther than the points where it meets the periphery of the earth's disk, which represent the times of sunrise and sunsetting.

Practical Astronomy

N. B. If the sun's declination had been south, the diurnal path of Edinburgh would have been on the upper side of the line VI. K VI. If the latitude of the given place were south, in which case the southern half of the earth's disk would be represented, the diurnal path between six in the morning and six in the afternoon would be between the line VI. K VI. and the centre of the disk, when the sun's declination was south, and the contrary when north. It is requisite to divide the horary spaces into quarters as in the figure, and if possible into minutes also.

In the present case the northern half of the axis of the moon's relative orbit lies to the left hand of the axis of the ecliptic. Make CB the radius of a line of chords on the sector, and taking therefrom the chord of 5° 43′, the inclination of the moon's relative orbit to the ecliptic, set it off from H to M on the left hand of CH, the axis of the ecliptic; then draw CM for the axis of the moon's orbit, and take the moon's latitude 26′ 2″ from the scale CA in your compasses, and set it from C to *y* in the line CH, and through *y* draw the straight line N*y*S at right angles to the axis of the moon's orbit CM for the path of the penumbra's centre over the earth's disk.

Take the moon's horary motion from the sun, 27′ 44″, in your compasses, from the scale CA (every division of which is a minute of a degree), and with that extent make marks along the path of the penumbra's centre, and divide each space from mark to mark into 60 equal parts or horary minutes by dots; and set the hours to every 60th minute in such a manner that the dot signifying the instant of new moon by the tables may fall into the point Z, half-way between the axis of the moon's orbit and the axis of the ecliptic; and then the rest of the dots will show the points of the earth's disk, where the penumbra's centre is at the instants denoted by them in its transit over the earth.

Apply one side of a square to the line of the penumbra's path, and move the square backwards and forwards, until the other side of it cuts the same hour and minute (as at 3 hours and 2$\frac{1}{2}$ minutes) both in the path of Edinburgh and in the path of the penumbra's centre; and the particular minute or instant so pointed out is the instant of the greatest obscuration of the sun, at the place for which the construction is made, namely, Edinburgh in the present example.

---

[1] Although a sector be a convenient instrument in these projections, yet it is not absolutely necessary. The intelligent student will be able to lay off an arc of any number of degrees, also to make an angle of a given number of degrees, in various ways.

Practical Astronomy.

Take the sun's semidiameter, 15′ 51″, in your compasses, from the scale CA, and setting one foot on the path of Edinburgh, at the point answering to the instant of the greatest obscuration, namely, at $2\frac{1}{2}$ minutes past three, with the other foot describe the circle UY, which represents the sun's disk as seen from Edinburgh at the greatest obscuration. Then take the moon's semidiameter, 14′ 50″, in your compasses, from the same scale, and setting one foot on the path of the penumbra's centre at the point $2\frac{1}{2}$ minutes past three, describe the circle TX for the moon's disk as seen from Edinburgh at the time when the eclipse is at the greatest, and the portion of the sun's disk which is hid or cut off by the moon's will show the quantity of the eclipse at that time; which quantity may be measured on a line equal to the sun's diameter, and divided into 12 equal parts for digits. As the moon's disk is entirely contained within the sun's, the eclipse as seen from Edinburgh will be annular.

Lastly, take the sum of the semidiameters of the sun and moon, 30′ 41″, from the scale CA, in your compasses; and setting one foot in the line of the penumbra's centre path, on the left hand from the axis of the ecliptic, direct the other foot toward the path of Edinburgh, and carry that extent backwards and forwards till both the points of the compasses fall into the same instants in both the paths, and these instants will denote the time when the eclipse begins at Edinburgh. Then do the like on the right hand of the axis of the ecliptic; and where the points of the compasses fall into the same instants in both the paths, they will show at what time the eclipse ends at Edinburgh.

Practical Astronomy.

These trials give $35\frac{1}{2}$ minutes after one in the afternoon for the beginning of the eclipse at Edinburgh at the points N and O, $2\frac{1}{2}$ minutes after three for the time of greatest obscuration, and $23\frac{1}{2}$ minutes after four at R and S for the time when the eclipse ends, according to apparent time. To have the mean time, or that shown by well-regulated clocks and watches, apply the equation of time in the contrary manner to that used for converting the mean time of new moon into apparent time. Therefore, in the present instance, subtract 3 minutes 56 seconds, or 4 minutes approximately, from the apparent times, and we have

	H.	M.	
Beginning of eclipse at Edinburgh,	1	$31\frac{1}{2}$	P. M.
Greatest obscuration	2	$58\frac{1}{2}$	—
End of eclipse.....	4	$19\frac{1}{2}$	—

all according to mean time.

The Projection of Lunar Eclipses.

When the moon's mean distance from either of her nodes at the time of mean full moon is less than 13° 21′ there may be an eclipse of the moon; but if greater, there cannot be an eclipse.

We find by Example II. that at the time of mean full moon in September 1830, the moon's mean distance from the descending node is only 1° 20′ 33″, which being so much less than the limit, there will then be an eclipse.

By Problem V. find the true anomalies of the sun and moon, and the moon's true distance from the ascending node, at the true time of full moon.

	Moon's True Anomaly,				Sun's True Anomaly,				Moon's True Distance from Ascending Node,			
	At True Full Moon.											

The elements for constructing an eclipse of the moon are eight in number, as follows:

1. The true time of full moon, and at that time; 2. the moon's horizontal parallax; 3. the sun's semidiameter; 4. the moon's; 5. the semidiameter of the earth's shadow at the moon; 6. the moon's latitude; 7. the angle of the moon's visible path with the ecliptic; 8. the moon's true horary motion from the sun. Therefore,

1. *To find the true time of full moon.* Work as already taught in the precepts. Thus we have the true time of full moon in September 1830 (see Example II.) to be the 2d day at $10^h.\ 36^m.\ 47^s.$ mean time at Greenwich.

2. *To find the moon's horizontal parallax.* Enter Table XXIII. with the moon's true anomaly $10^s.\ 6°\ 29'\ 25''$, and thereby take out her horizontal parallax; which, by making the requisite proportions, will be found to be 59′ 52″.

3. 4. *To find the semidiameters of the sun and moon.* Enter Table XXIII. with the sun's mean anomaly and moon's true anomaly ($8^s.\ 1°\ 33'\ 0''$ and $10^s.\ 6°\ 29'\ 25''$), and thereby take out their respective semidiameters, the sun's 15′ 54″, and the moon's 16′ 19″.

5. *To find the semidiameter of the earth's shadow at the moon.* Add the sun's horizontal parallax, which is always 9″, to the moon's, which in the present case is 59′ 52″; the sum is 60′ 1″, from which subtract the sun's semidiameter, 15′ 54″, and the remainder, 44′ 7″, being increased by 50″ for the effect of the earth's atmosphere, we have 44′ 57″ for the semidiameter of the earth's shadow, which the moon then passes through.

Practical Astronomy

6. *To find the moon's latitude.* Proceed as already directed under the prediction of solar eclipses. Thus,

	s.	°	′	″	+ s.	— s.
Argument, Table XVII.	5	29	50	14	52	
XVIII.	4	6	39			10
XIX.	2	13	9		25	
XX.	4	6	20		14	
XXI.	1	29	43		17	
XXII.	2	0	2		28	
					+ 2 16	— 10
					—10	

Moon's latitude north + 2 6

7. *To find the angle of the moon's visible path with the ecliptic.* Enter Table XVII. with the moon's true distance from the ascending node for argument, and the angle is found to be 5° 44′, left, signifying that the axis of the moon's orbit is to the left hand of the northern axis of the ecliptic.

8. *To find the moon's true horary motion from the sun.* With the true anomaly of the moon and the mean anomaly of the sun, take out their horary motions from Table XXIII., and the sun's horary motion subtracted from the moon's leaves remaining the moon's true horary motion from the sun; in the present case 33′ 58″.

These elements being found for the construction of the moon's eclipse in September 1830, proceed as follows:

Draw the line ACB for part of the ecliptic, and CD perpendicular thereto for the northern part of its axis, the moon having north latitude. (Plate XCI. fig. 137.)

Add the semidiameters of the moon's and earth's shadow together, which in the eclipse make 61′ 16″; and take this in your compasses, from a scale of equal parts, and setting one foot on the point C as a centre, with the other foot describe the arch ADB, in one point of which the moon's centre will be at the beginning of the eclipse, and in another at the end thereof.

Take the semidiameter of the earth's shadow, 44′ 57″, in your compasses, from the scale, and setting one foot in the centre C, with the other foot describe the semicircle KLM for the northern half of the earth's shadow; because the moon's latitude is north in this eclipse.

Subtract the semidiameter of the moon from the semidiameter of the earth's shadow, and the remainder is 28′ 38″, which take in your compasses from the scale, and setting one foot on the point C as a centre, with the other foot describe the arch OPQ; in one point of which the moon's centre will be at the beginning of total darkness, and in another at the end thereof.

Draw the line CE on the left hand of the northern axis of the ecliptic, and making an angle of 5° 44′ therewith, which line represents the northern part of the axis of the moon's orbit, the moon's latitude being north. Practical Astronomy

Take the moon's latitude, 2′ 6″, from the scale with your compasses, and set it from C to G in the axis of the ecliptic, and through the point G draw the straight line RSGTU, at right angles to the axis of the moon's orbit, for the path of the moon's centre. Then F, in the line CE, is the point in the earth's shadow where the moon's centre is at the middle of the eclipse; G, the point where her centre is at the instant of her ecliptical conjunction; and the middle between them, the point where her centre is at the time of true full moon by the tables.

Take the moon's horary motion from the sun, 33′ 58″, in your compasses, from the scale, and with that extent make marks along the line of the moon's path; then divide each space from mark to mark into 60 equal parts or horary minutes, and set the hours to the proper dots, in such a manner, that the dot signifying the instant of full moon (36 minutes and 47 seconds after ten) may be midway between the points F and G.

The point U, where the moon's path intersects on the right hand the arch described with the sum of the semidiameters of the moon and earth's shadow, denotes the instant when the eclipse begins, namely, at 52 minutes after eight; the point T, where the moon's path intersects on the right hand the arch described, with the difference of the semidiameters, denotes the instant when the moon's total darkness begins, namely, at 48 minutes after nine; the point F denotes the middle of the eclipse at 39 minutes after 10; the point S, where the moon's path intersects on the left hand the arch described, with the difference of the semidiameters, denotes the end of the moon's total darkness at 30 minutes after eleven; and the point R, where the moon's path intersects the arch described, with the sum of the semidiameters, denotes the end of the eclipse at 26 minutes after 12, all mean time according to the meridian of Greenwich. If the times reckoned by any other meridian are required, apply the longitude from Greenwich to the Greenwich times, by addition or subtraction, according as the place is east or west of Greenwich.

On F as a centre, with a radius equal to the moon's semidiameter, describe a circle which represents the moon's disk at the middle of the eclipse.

The line VX denotes the quantity eclipsed at the middle of the eclipse, which may be measured on a line equal to the moon's diameter, and divided into equal parts for digits. In the present case, the eclipse being total, the quantity eclipsed is said to be greater than the moon's diameter, and is found to be $21\frac{1}{3}$ digits.

CHAPTER III.

CATALOGUE OF FIXED STARS, AND TABLE OF REFRACTIONS.

SECT. I.—*Right Ascensions and North Polar Distances of* 652 *Stars, extracted from the Greenwich Twelve-Year Catalogue of* 2156 *Stars, and reduced to the epoch* 1850, *January* 1; *with the Annual Variations, including the Geometrical Precessions given in the British Association Catalogue, and the Proper Motions given in Mr* MAIN's *Paper in vol. xix. of the Memoirs of the Royal Astronomical Society.*

No. 66, ι Persei. The proper motion of this star in R. A. given in the *British Association Catalogue*, is + 0ˢ·129; this probably results from some error, and is not included in the annual variation.

Explanation of the Table of Refractions.

This table is computed upon principles explained by the late Dr Young in the *Philosophical Transactions* for 1819; and it appears to agree more perfectly with the latest observations than any other table before published.

The apparent altitude being found in the first column, the second shows the refraction when the barometer stands at 30 inches, which is its mean height on the level of the sea, and the thermometer at 50° of Fahrenheit. The third column contains the difference to be subtracted or added for every minute of altitude, reckoned from the nearest number in the first column. The fourth shows the number of seconds to be added for every inch that the height of the barometer exceeds 30, or to be subtracted for each inch that it wants of 30: and the last contains the number of seconds to be subtracted for each degree that the thermometer stands above 50°, or to be added for each degree that its height wants of 50°.

If great accuracy be required, we must also deduct from the observed height of the barometer ·003 inch for each degree that the thermometer near it is above 50°, and add an equal quantity for an equal depression. In fact, however, the table, as it now stands, is found to require the temperature to be estimated from the height of the thermometer within; and if we employed the height of the thermometer without, which would be more consistent with the theory, it would probably be necessary to suppose the standard temperature of the table 48° only (or rather 47°), instead of 50°.

Examples.

1. At 7° 18′ 13″, barometer 29·87, thermometer 66°, the refraction is 6′ 52″·26, from twenty-two observations of Bradley.

2. At 19° 18′ 19″, barometer 30·045, thermometer 34°, the refraction is 2′ 51″·5, from three observations of Bradley.

3. At 13° 43′, barometer 29·85, thermometer 45°, the refraction is 3′ 55″·85, from 156 observations of Mr Pond.

Practical Astronomy

CHAP. IV.

ASTRONOMICAL INSTRUMENTS.

There are two principal objects to be accomplished by astronomical instruments; the one is the extension and improvement of the science; and the other its application to geography, navigation, and the ordinary wants of society. Here we give the name astronomical instruments to such as in their application are directed to the heavenly bodies, as a telescope is directed to a star, and the axis of a sun-dial to the pole; but we do not consider as astronomical instruments *orreries*, and machines composed of wheels and pinions, such as exhibit imperfectly representations of the celestial motions. Globes are indeed appropriate furniture in an observatory, because they truly exhibit the relative positions of the stars and the different countries; and they serve to resolve approximately the different problems of the sphere. But complex orreries and planetary clocks are mere playthings. They excite admiration by the ingenuity displayed in their construction, but they are of no practical use. Showmen pretend to teach astronomy by their assistance; but their inutility in giving just notions of the dimensions and magnitudes of the bodies which form the solar system may be easily conceived by reflecting, that if in an orrery the earth be represented by a sphere one inch in diameter, the representation of the sun should be nine feet; also, that if the representation of Mercury describe a circle of about four inches radius, then the orbit of Uranus should have its radius sixteen feet.

Judicious teachers of astronomy may, however, employ with advantage simple contrivances to facilitate the acquiring of correct notions of the celestial motions; but they will direct the attention to a single object at a time, and not attempt to exhibit all the phenomena of the heavens at once. Wooden wheels and catgut bands are just as useful for the purpose in question as metallic wheels and pinions. A globe moved by the hand round a candle will serve to show the changes of the seasons; and in like manner the phases of the moon, her nodes and their motion, and the nature of eclipses, may be all explained by simple and easy contrivances.

1. *Astronomical Telescope.*

In a subsequent part of this work the theory of the telescope, and the various kinds of telescopes, will be fully explained. As, however, the telescope forms an essential part of almost all complex astronomical instruments, it will be proper to explain here in a general way its principles and use.

The astronomical telescope is composed of two principal parts, the *object-glass*, and the *eye-glass* or *eye-piece*. These are in opposite ends of a tube; and in its application the former is next the object, and the latter next the eye. In telescopes of the best construction the object-glass is composed of two and sometimes of three pieces. (See ACHROMATIC GLASSES.) We shall here, however, suppose it of the simplest form; that is, a very thin double convex glass, the opposite sides being portions of spherical surfaces.

Let ABDE (Plate XC. fig. 131) be a lens of this form, C being the centre of a sphere, of which ABE is a portion of the surface. Let L be any point in an object to be viewed with the telescope, and let a ray of light proceeding from L fall perpendicularly on the convex surface in B: it will pass through the glass without being turned out of its direction, and will proceed straight forward on the prolongation of the line LBD.

Let another ray LI fall obliquely on the convex surface at I: by the principles of optics this will be *refracted*, that is, turned out of the direction LI, and take a new direction IP. Draw CI to the centre; the new direction will be such that the sine of the angle of incidence MIL or CIL will be to the sine of the refracted angle CIP in the constant ratio of a given number n to 1. Practical Astronomy

We have therefore

$$n = \frac{\text{sin. CIL}}{\text{sin. CIP}} = \frac{\text{sin. CIL}}{\text{sin. ICL}} \cdot \frac{\text{sin. ICP}}{\text{sin. CIP}} = \frac{\text{CL}}{\text{IL}} \cdot \frac{\text{IP}}{\text{CP}}.$$

Let us suppose the point I to be near B; then IP=BP nearly, and IL = BL nearly, and we have

$$n = \frac{\text{CL} \cdot \text{BP}}{\text{BL} \cdot \text{CP}}, \text{ nearly} \ldots\ldots\ldots\ldots (1)$$

When the ray arrives at the concave surface ADE, it suffers a second refraction in passing into the air, and changes its direction from IP into a new direction IL'. Let C' be the centre of a sphere, of which ADE is a part of the surface: draw the radius C'I', and we shall have sin. C'I'L' : sin. C'I'P :: n : 1; and therefore

$$n = \frac{\text{sin. C'I'L'}}{\text{sin. C'I'P}} = \frac{\text{sin. C'I'L'}}{\text{sin. I'C'L'}} \cdot \frac{\text{sin. I'C'P}}{\text{sin. C'I'P}} = \frac{\text{C'L'}}{\text{I'L'}} \cdot \frac{\text{I'P}}{\text{C'P}}.$$

We suppose the arcs IB, I'D, to be small; therefore I'P = PD nearly, and I'L' = DL' nearly; hence

$$n = \frac{\text{C'L'} \cdot \text{PD}}{\text{DL'} \cdot \text{C'P}}, \text{ nearly.}$$

Since the thickness of the lens is supposed to be inconsiderable, we may assume that PD = PB nearly, and that DL' = BL nearly, and then we have

$$n = \frac{\text{C'L'} \cdot \text{PB}}{\text{BL'} \cdot \text{C'P}} \ldots\ldots\ldots\ldots (2)$$

Let r = CB, r' = C'B, Δ = BL, Δ' = BL', v = PB, and equations (1) and (2) become

$$n = \frac{v(r+\Delta)}{\Delta(v-r)}; \qquad n = \frac{v(r'+\Delta')}{\Delta'(v+r')};$$

from these we obtain

$$\frac{n}{v} = \frac{n-1}{r} - \frac{1}{\Delta}, \text{ and } \frac{n}{v} = \frac{1}{\Delta'} - \frac{n-1}{r'};$$

and hence

$$\frac{1}{\Delta} + \frac{1}{\Delta'} = (n-1)\left\{\frac{1}{r} + \frac{1}{r'}\right\}.$$

When a ray of light passes out of air into glass, the sine of the angle of incidence is to the sine of the angle of refraction as 3 to 2 nearly, or as $1\frac{1}{2}$ to 1. In this case $n = 1\frac{1}{2}$, and

$$\frac{1}{\Delta} + \frac{1}{\Delta'} = \tfrac{1}{2}\left(\frac{1}{r} + \frac{1}{r'}\right).$$

This expression will be the very same if we put r instead of r', and r' instead of r; also, if we put Δ for Δ', and Δ' for Δ. Hence we may infer, that whichever of the two convex sides of the object-glass be turned towards the object L, the value of Δ' will be the same for a given value of Δ; also, that if L' be the *focus* to which rays issuing from L converge after refraction, then L will be the focus to which rays issuing from L' would converge after passing through the object-glass.

If Δ, the distance of L from the object-glass, be very great, then $\frac{1}{\Delta}$ will be very small in respect of $\frac{1}{\Delta'}$; and in the case of the heavenly bodies $\frac{1}{\Delta}$ vanishes, and we have simply

$$\frac{1}{\Delta'} = \tfrac{1}{2}\left(\frac{1}{r} + \frac{1}{r'}\right).$$

If we suppose both sides of the object-glass to be alike convex, that is, $r = r'$, then $\Delta' = r$; hence we learn, 1*st*, that all rays which come from any point whatever of a

Practical Astronomy.

very remote object, and which traverse a double convex glass of equal curvature on both sides, are united by refraction about its centre of sphericity, which is called its *principal focus*; 2*d*, that rays which proceed from a point at the centre of sphericity do, after refraction, proceed in lines which may be considered as parallel. All these conclusions are only true approximately. They suppose the convex arcs ABE ADE small, and the thickness of the glass very little; nevertheless they differ but little from truth: the focus L is not indeed a mathematical point, but has a certain magnitude, which varies with the distance of the object and the breadth of the lens.

If we now suppose that two lenses, BD, *bd* (fig. 132), are adapted to the extremity of a tube, so that their centres of sphericity coincide at the same point F, and that this point and the centres of the lenses are in the same straight line, then, from what has been explained, it follows that rays coming from a distant object L, after passing through the lens BD or object-glass, will be collected at F (which is therefore called the *focus of parallel rays*), and will there form an image of the object L: also, that all the rays, after crossing in the focus F, will proceed forward; but in passing through the second lens or *eye-glass bd*, they will be again refracted, and emerge on the other side in parallel lines; and if they enter an eye now situated at O, these parallel rays will produce distinct vision.

The eye does not see directly the remote object AC, but only its image formed at the focus F, and this in respect to the object is inverted; for the rays proceeding from A and falling on the object-glass at B, are by refraction turned into the direction BF, and meet the glass at δ. In like manner, the rays which are emitted from C, and pass through the object-glass at D, meet the eye-glass on the opposite side at β: thus the object AC and its image formed at F have opposite positions.

The astronomical telescope, then, differs from the common telescope for viewing objects at a distance, in reversing the position of objects seen through it, also the direction of their motions, the upper limb of the sun or moon appearing the lower, and all the heavenly bodies appearing to move from west to east. This, which would be an inconvenience with terrestrial objects, is of no consequence in viewing the stars.

The surface of the object-glass being always much greater than that of the eye-glass, which has a shorter focus, and all the rays which fall on the surface BD of the former being collected on the surface *bd* of the latter, they are there condensed, and the illumination is increased in the inverse proportion of the areas of the glasses; so that if the intensity of the light which falls on the object-glass be represented by 1, that on the eye-glass will be $\left(\frac{BD}{bd}\right)^2$; hence telescopes in general render objects more luminous and more easily distinguished. They also magnify objects; for let A be the centre and B the border of an object (fig. 133). The point A is visible to the eye O, by the ray AD*a*EO which traverses the object-glass D and eye-glass E, but suffers no refraction. (We here do not consider the oblique rays, which, proceeding from A, are collected at the principal focus.) The border B is visible by the ray BD*b* at the focus *b* of the object-glass. This ray meets the eye-glass at *d*, and is there turned by refraction into the direction *de*; and, in emerging from the glass at *e*, is again refracted to O, its focus, so that OE is parallel to E*b*. The image is seen under the angle *e*OE = *b*E*a*: but *ab* = D*a* tan. D, therefore

$$\text{tan. E} = \frac{Da}{Ea}\,\text{tan. D} = \frac{R}{r}\,\text{tan. D, or E} = \frac{R}{r}\,D;$$

R being the radius of sphericity of the object-glass, and *r* that of the eye-glass. The angle under which the object is seen is therefore increased in the proportion of the two radii, and the magnifying power is the greater, as the radius of the eye-glass is less than that of the object-glass.

Practical Astronomy

Common astronomical telescopes generally magnify from 70 to 100 times; some even magnify 300 times. This, however, must not be understood in a rigorous sense; if, for example, we expect to see the moon 100 times larger with a telescope which is said to magnify 100 times, we may be disappointed. To produce this effect, the telescope ought to magnify more: it only represents the moon under an angle 100 times greater; but it is not by the visual angle alone that we judge of magnitude; our opinion is greatly influenced by the distance at which we suppose the object. When we see an object under the angle AKB (fig 134), nothing determines whether this object is truly AB, or CD, or EFF; and according as we judge it to be in the first, or second, or third of these positions, or in one more remote, we assign to it magnitudes always increasing although the angle is still the same. But this judgment being uncertain, and such as cannot be subjected to calculation, the magnifying power of a telescope is in practice estimated by the angle of vision, which can always be exactly determined.

Let F be the principal focus of the object-glass C (fig. 135). If the angle HCG is such, that HG (=2 HF)=2 CF tan. HCF is equal to the diameter of the interior tube of the telescope, the angle HCG is called the *field of view*: every object whose focal image is greater than HG cannot be seen entirely in the telescope. This happens in the case of the sun and moon when viewed with telescopes of about $8\frac{1}{2}$ feet, such as are used in considerable observatories. In these, the sun's image will be about $9\frac{1}{2}$ inches. This exceeds the diameter of the tube. But the opening is yet more contracted by a perforated diaphragm, which, besides other purposes, serves to cut off the rays irregularly reflected from the inside of the tube, also those which produce colour in the image. To determine the field in view as limited by the diaphragm, then, we have this equation; $2\,\text{tan. HCF} = \frac{HG}{CF} = \frac{2\,HF}{CF}$. If we put *r* for HF, the radius of the diaphragm, and R for CF, the radius of sphericity of the object-glass, the field of view in seconds is $\frac{2r}{R \sin. 1''}$.

2. *Dorpat Telescope.*

The late Joseph Fraunhofer of Munich, a most skilful artist and experimenter in optics (whose demise in 1826, in the prime of life, was a great loss to science), constructed a magnificent refracting telescope for the observatory of the Imperial University at Dorpat. It was received by Professor Struve in the year 1825, and has since been found to fulfil most satisfactorily his expectation and the intentions of the maker. As this is one of the most magnificent instruments of the kind that has hitherto been constructed, and described by a figure, we have given an engraving of it, copied from the *Memoirs of the Astronomical Society*. (See Plate XCII.)

The object-glass of this telescope is about $9\frac{1}{2}$ inches in diameter, and its focal length about 14 English feet. The main tube is 13·8 feet; and, in addition, there is the small tube which holds the eye-pieces. Of these there are four; the least magnifying power is 175, and the greatest 700. After the telescope was received at Dorpat, a perfect micrometrical apparatus was ordered to be made for it. This was to consist of four annular micrometers, of which two were to be double; a lamp circular micrometer, with four

Practical Astronomy.

eye-pieces; a refracting lamp net micrometer, with position circles, and four eye-pieces.

The frame-work of the stand is made of oak, and the tube of deal, veneered with mahogany. The whole weight of the telescope and its counterpoises is supported at one point, namely, at the common centre of gravity of all the ponderous parts. These weigh 3000 Russian pounds, of which the frame-work contains 1000; the remaining 2000 are so balanced in every position, that the telescope may be turned, with ease and certainty, in every direction towards the heavens.

The basis of the frame is formed of two cross beams, each nine feet seven inches long. The ends of these are seen in the figure at A, B, C, D. They are braced by four smaller bars forming a square, one of which is seen at E. This braced cross is fastened to the floor by eight screws, six of which are seen in the figure. A perpendicular post, about six feet high and seven inches square, is fixed over the centre of the cross, and is propped at the north, east, and west sides by three curved stays, denoted by G, G′, G″, which are fixed at their lower ends to the beams of the cross, and at the upper to the vertical post. An inclined beam H of the same thickness rests on the southern end of the meridian beam of the cross, and is attached to the vertical beam in a position parallel to the polar axis. This axis, shown in the figure at I, is a cylinder of steel 39 inches long, and proportionally thick. It turns in two collars, and its lower end, which is rounded and polished, rests on a steel plate attached to the bearing piece K, which is secured to the inclined beam H, and has therefore very little friction, the weight being supported by friction rollers near the common centre of gravity; and a counterpoise L is applied to support the axis in any position. There is a circle 13 inches in diameter, graduated to minutes of time, fixed to the lower end of the axis, and furnished with verniers. The axis of vertical motion of the telescope, which has nearly the dimensions of the polar axis, passes through a brass tube at right angles to the latter; the tube, which is seen at M, forms a part of the frame, and is fastened to the upper end of the polar axis by twelve screws. This axis carries the circle of declination, which is 19 inches in diameter, and is divided to every 10′, with a vernier reading 10″ or 5″ by estimation. The tube of the telescope is fixed to the frame-work nearer to the eye end than the middle, and has two counterpoises attached to levers, which balance the two ends, and prevent the natural tendency of the longer end to bend. The brass frame holding the two axes appears on the figure clamped to the tube by two strong rings, one at each end of the centre of motion. A bent lever, carrying the weight O, embraces by a double ring the near end of the axis of the declination circle. The axis itself carries another weight; and by this and the weight O it is counterpoised. The slow motion in altitude is given to the telescope by a Hooke's joint applied to the screw of the clamp, which has a spring urging it against a strong iron bar P, attached to the end of the cylinder M, that forms a stop to the circle; and a slow equatorial motion is given by a second Hooke's joint taking hold of an endless screw, acting with the racked edge of the hour circle, while a spring presses it into action uniformly, and a lever is employed to raise it out of the rack when necessary. The handles taking hold of these screws extend to the reach of the observer, who can thus point his telescope in right ascension and declination with the same certainty as the best meridian instrument.

A regular sidereal motion is communicated to the instrument by clock-work, which keeps a star apparently at rest in the centre of the field of view; and there is a contrivance by which the sidereal can be changed into a solar, also to a lunar angular motion.

Practical Astronomy.

This almost invaluable instrument cost 10,500 florins (about 950 pounds sterling). The price, although it may appear considerable, yet barely covered the expense of the workmanship of its construction. This relinquishment of the profit of trade does great credit to the ingenious and liberal-minded artists, Fraunhofer, and Utzelmeider, the chief of the optical establishment at Munich.

3. *Lord Rosse's Reflecting Telescope.*

This celebrated telescope has two object-mirrors of 6 feet in diameter, and of 53 feet focal length. The preparations for the casting were commenced in 1842 and many experiments were necessary before the best proportions of tin and copper, of which the alloy for the mirrors was composed, were discovered. The respective weights of the specula are $3\frac{1}{2}$ and 4 tons, and the most refined precautions were necessary in the construction of the furnaces for fusing these immense masses of metal, in transferring it to the moulds prepared for the casting, and in cooling it with the requisite degree of slowness, to prevent flaws or cracks. The polishing process was performed by causing the polishers to make strokes backwards and forwards in imitation of the manner in which the hand would perform the same process by means of the action of a small steam-engine. This engine gave motion to a beam, which, by the intervention of a crank and connecting rods, gave motion to the polishers. A very ingenious system of levers was devised for the support of the mirror, so that it should remain in every required position without strain. Three similar systems of these levers rest on fulcra immediately under the centres of gravity of the three equal sectors into which the surface of the mirror may be supposed to be divided. Each system consists of one triangle with its point of support directly under its centre of gravity, on which it freely oscillates, and each triangle carries at its angles other three triangles similarly supported; and finally, at each angle of these last-named triangles, are placed three balls rotating freely, on which the mirror ultimately rests.

The tube of the telescope provided for the use of these enormous mirrors is of wood, fixed to a cube of 10 feet, which has in one of its sides folding doors for the admission of the specula. The specula themselves are placed on frames which run on railroads leading into this cube, these frames being the same on which they were cast and polished.

The telescope is placed between two immense piers 70 feet long and nearly 50 feet high, which serve as supports for the apparatus necessary for giving the requisite elevations of the tube, and for directing it to a given object, and also for the galleries which carry the observer near its upper end. It carries near its upper extremity the apparatus for the Newtonian small mirror, though provision has been made in the construction of the observing galleries for its use as a Herschelian telescope, without a second reflexion, for the purpose of avoiding loss of light.

The observations made with this wonderful instrument have been chiefly confined to nebulæ, in many of which some remarkable discoveries have been made. In the *Phil. Trans.* for 1850, are some beautiful drawings of some of these mysterious structures, amongst which the spiral forms of Messier 51 and Messier 99 deserve particular attention.

4. *Transit Instrument, Meridian Circle, and Astronomical Clock.*

The primary problem in geography is to determine the exact position of any proposed point on the earth's surface in respect of the equator and some assumed meridian, as that of Greenwich or Paris; that is, to find its latitude and

Practical Astronomy

longitude. The corresponding problem in astronomy is to determine the position of every fixed star, and in general of any celestial object. in respect to the equinoctial circle in the heavens (or else the pole) and a circle passing through the pole and the intersection of the equator and ecliptic; that is, to find its *declination* or polar distance, and its *right ascension* (chap. i. sect. i.) The former of these is found in great observatories by the *mural circle*, and the latter by the *transit instrument* or *transit circle*, and the clock.

The first transit instrument of which we have any account was that of Roemer, which he described in 1700. (*Miscel. Ber.* tom. iii.) Dr Halley placed a transit instrument in the Greenwich observatory in 1721. The axis was iron, and the telescope about five feet in length. This has been long laid aside, but is still preserved as a relic. Transit instruments of the present day are of two forms; one, the most common, is adapted to the determination of the right ascension only, the other to the determination of both right ascension and declination, either at once or by separate observations.

We have selected for description the transit instrument now in Sir James South's observatory at Kensington, which was constructed for him in 1820, by Troughton, with all the care that artist could bestow on it; and which, as far as the just proportions of its parts are concerned, he regarded as his happiest production. The instrument, with its various parts, is represented in Plate XCIII. Figures 1 and 3 represent two views of it. EO is an achromatic telescope, of which E is the end next the eye; AA′ is its axis of motion, with which the tubes are closely united at their junction, so as to form but one body. The extremities of the axis rest in notches formed on two cheeks of metal at AA′, which are firmly attached to the inner faces of two stone pillars PP′; and B, B′, B″, B‴, are four braces connecting the tubes and axis. These are the parts of the instrument which, on inspection, immediately meet the eye. When adjusted, the axis of motion of the instrument is truly horizontal and perpendicular to the plane of the meridian, and the optical axis of the telescope is in the plane of the meridian; the object of the whole construction is to keep it precisely in that plane, whatever position be given to the telescope by turning on its axis.

The object-glass of the telescope has four inches of clear aperture, and its focal length is seven feet two inches. The body of the telescope and the axis are formed of conical tubes firmly united in a spherical centre-piece, on which their wider ends rest, and cover two-thirds of its surface: thus the tube of the telescope is formed of two pieces, which taper towards its extremities, where their diameters are nearly the same as that of the object-glass. The axis in like manner tapers equally towards its extremities.

The centre-piece is perforated in the direction of the telescope, and also in that of the axis; the width of the first opening being a little more than the radius of the object-glass, and that of the second just enough to allow the light of a lamp placed near the end of the axis to pass uninterruptedly to the centre illuminator. The ends of all the four cones, where they join the sphere, are strengthened by circular pieces of cast brass, which extend full four inches into the cones, and are fixed by solder and pins. They are turned concave in front, so as to fit the surface of the sphere into which they are rabbeted, and serve to keep the opposite branches of the axis and telescope straight and perpendicular to one another; and to these pieces are attached rings for the reception of the screws which bind the whole together. The four branches of the axis and telescope are solely united by *tension bars*. These pass through the sphere, six in the direction of the axis and four in that of the telescope. They are arranged at equal distances between corresponding parts, but so as neither to obstruct the rays of the object-glass nor the light of the lamp that falls on the illuminator. They screw into the rings of the brass pieces which enter the cones. The tension bars serve a most important purpose in giving stiffness and permanence of form to the instrument; and he that would imitate it would do well to study Sir James South's description in the *Phil. Trans.* for 1826. Fig. 3 is a section through the axis, and exhibits the six bars which bind together the cones of the axis, and also the places of the four which are perpendicular to them, and which connect the tubes of the telescope. Fig. 4 is a section through the telescope; the bars of the telescope are shown lengthwise, whilst those of the axis are perpendicular. In both figures the illuminator within the telescope is shown, in one the polished surface, and in the other the back of the plate. The illuminator crosses the tube of the telescope at an angle of 45°. This position requires that the opening in it, through which the light coming through the object-glass passes, should be an ellipse. The braces B, B′, B″, B‴, extending from the cones of the axis to those of the telescope, are attached to the former about two inches from the pivots, and to the latter about ten inches from the centre-piece. They exert but a very slight pressure, and might have been omitted in this instrument. They were added in imitation of the Greenwich transit, to which they are essentially necessary.

Practical Astronomy

The apparatus for giving the telescope any required altitude is shown at the eye end in figures 1 and 2, but on a larger scale in fig. 5. It consists of two complete circles, six inches in diameter, firmly attached to the eye end of the telescope: each is provided with two opposite verniers, subdividing its divisions into minutes of a degree. The indexes have clamps and slow moving screws, and microscopes are attached to the verniers; a spirit level is also attached to the index of each circle. The apparatus is adjusted by setting the index to the place of the star, and then, the telescope being moved round till the bubble of the level stands in the middle of its range, the star will traverse the field between the two horizontal wires. If two stars differ but little in right ascension, as Capella and Rigel, so as not to allow time for changing the index which was set to the altitude of that which came first, then the index of the other circle may be set to the altitude of the following star, and both observed. When the same object is to be observed by direct vision, and also by reflexion, then one of the indexes may be set to point the telescope to the direct place of the star, and the other to its reflected image.

Figures 7 and 8 exhibit the plates or side-pieces, and Ys in which the pivots of the axis rest. The plates, which are semicircular, are imbedded in the stone piers, and are firmly screwed to them. Figure 7 represents the eastern plate, in which the contrivance for placing the axis truly level is contained. This adjustment is made by a piece of which the upper end is formed into a Y, and which may be moved vertically, but not laterally. To raise or depress it gradually, there is a piece having a short cylindrical part in the middle; also a fine screw at its upper end, which works in the moveable piece, and a coarse screw at its lower, which works in the fixed plates. The cylinder has holes by which it can be turned round by a capstan pin. By the ingenious contrivance of the two screws, the sliding piece is moved vertically, but slowly; for the space gone through is only the difference of the spaces through which it would have been pushed or drawn by each screw acting by itself. Fig. 8 shows the western plate. In this the Y piece admits only of a horizontal motion for the purpose of placing the instrument in the meridian. The adjustment is effected by two screws, which work in the opposite sides of the piece, and whose heads abut against the fixed plate. To produce motion one of them must be screwed and the other unscrewed by equal

Practical Astronomy

quantities while the observer's eye is at the telescope; and to effect this the screws are connected by pinion work put in motion by a handle hanging down close to the inside of the western pier. (See fig. 1.)

Fig. 9 is a bird's-eye view of the head of one of the piers. This is meant to show the apparatus for relieving the pivots of the axis and the Ys from a great part of the weight which would otherwise bear on them. Immediately behind the adjustable Y piece, but rather broader, is a plain piece of brass having a Y cut in its upper end: a lever also is seen, one extremity of which passes into a hole made in this Y piece, while the other end carries a weight. The bar of the lever is expanded into a circle whose centre is about one third of the lever's length distant from the pivot of the axis. The circle admits the illuminating lantern. Two steel screws, with blunted, hard, and polished points, are inserted in the diameter at right angles to the direction of the lever: these rest on hardened and polished planes, which are let into the stone pier, and together form the fulcrum, in the manner of a balance. The weight is a short cylinder hooked on the end of the lever: it is hollow to receive small shot, introduced, as a counterpoise, to relieve, more or less at pleasure, the instrumental portion of the pivot, and also the instrumental Y piece, of weight.

Fig. 6 is a perspective view of the eye end of the telescope. In it a micrometer is shown, which moves a plate contiguous to that in which the five transit wires are inserted: one wire is contained in the moveable plate, and is intended to facilitate the observation of the pole-star and others near it.

In fig. 1, on the eastern side of the telescope, a projecting finger-screw is seen. This gives motion to an apparatus within the tube of the telescope for regulating the quantity of light projected by the illuminator on the transit wires.

The Greenwich transit instrument, also the workmanship of Troughton, and one of his much admired productions, was placed in that observatory in 1816. In its construction it is nearly the same as Sir James South's, but of different dimensions. The object-glass of the telescope is 5 inches in clear aperture, and the focal length 10 feet: its horizontal axis, including the pivots, is 3 feet 10 inches. This instrument was dismounted in the year 1851, and its use was replaced by that of the great transit circle. For a more detailed account the reader may consult the volumes of the *Greenwich Observations*.

All transit instruments have a *meridian mark*, that is, a mark on some remote object, by which it may be ascertained at any time whether the instrument be truly in the meridian.

Transit or meridian circles are in their nature quite analogous to the instruments we have described; with, however, the important addition of a graduated circle of considerable dimensions as a principal part of their construction. The meridian circle which Troughton constructed for Mr Groombridge, but which afterwards passed into the hands of Sir James South, is a fine example of this kind of instrument. A figure and description of it may be seen in Dr Pearson's valuable work on Practical Astronomy. The largest and finest instrument at present is that which was erected at Greenwich in 1850.

A clock of the very best construction is an indispensable companion of the transit instrument. This may be regulated so as to show either mean solar or sidereal time, according to the principal objects in view, the one being always easily convertible into the other. The attention of ingenious men has been long directed to the construction of the astronomical clock; but on this subject we shall have occasion to treat fully elsewhere in our work.

The transit instruments here described are of the most expensive kind, and adapted to the higher efforts in the cultivation of astronomy; but there are also portable transits which travellers may use, and which may serve to determine true time. In all applications of the instrument, the axis must be placed truly horizontal by means of the level; the line of collimation, that is, a line between the centre of the object-glass and the centre of the cross wires, must move in a great circle, or, which is the same thing, it must be perpendicular to the axis; and the vertical circle which it describes must be the meridian: these are the three principal adjustments. The *Nautical Almanac* gives the exact time when the sun or certain considerable stars pass the meridian. The observer gives the telescope such a position that the star must appear in the field of view in its passage. When it is seen, he notes the exact time, by the beat of the clock, when it crosses each wire. Of these wires there are generally five or seven in the focus of the eye-piece, and all transits (whether perfect or imperfect) are always reduced to the time of passage over an imaginary line corresponding to the mean of these.

Practical Astronomy

5. *The Mural Circle.*

The Royal Observatory at Greenwich has two *mural quadrants*, each about eight feet radius; these are fixed on a massive structure of hewn stone in the form of a parallelopiped, one on each side, and hence their name. That whose telescope is directed towards the north is chiefly of iron, and was erected by Graham in 1725, for the lunar observations of Halley: it was, however, redivided by Bird in 1753. The other, for the southern part of the meridian, is of brass, and was constructed by Bird, and placed in its position in 1750: with this Bradley and Maskelyne successively made their observations for forty-six years.

Experience had shown, early in the present century, that entire circles have a great advantage over quadrants; accordingly, the use of the Greenwich quadrants was discontinued, and in their stead a *mural circle* six feet in diameter, constructed by Troughton, was placed in the observatory on 12th June 1812. A second *mural circle*, nearly a copy of the other, constructed by Thomas Jones (another eminent artist), was, in 1825, placed in the observatory, fronting the former, and at a distance of seven feet to the east; and with these two instruments simultaneous observations were, during the administration of Mr Pond, daily made of the zenith distances of stars, the zenith point being obtained by a combination of observations made by direct vision and by reflexion in a trough of mercury. Soon after the accession of Mr Airy, the use of Jones's circle was discontinued, as we have before had occasion to mention.

Figs. 1 and 2 of Plate XCIV. give two views of Troughton's mural circle. In fig. 1 the circle is seen obliquely on the front or eastern face of the wall, with the greater part of its apparatus. The breadth of the wall from north to south is seven feet, its thickness from east to west four feet, and its height ten feet. It is formed of four stones laid one on another. The third stone has in its under side a semicircular groove, cut in its middle from west to east, of six inches radius. The upper side of the second stone being worked level, forms the diameter of this semicircular *arch-hole*, and supports the axis-work of the instrument at about five feet above the floor. The real centre of the instrument is about five inches higher. The nucleus of the Greenwich circle is an octagon of eight inches diameter at the corners; its depth is three inches, and a circular perforation of six inches and a half is made through its whole depth. The outward faces of the octagon, which are each three inches square, support eight of the circle's conical radii, to which they are screwed and steady-pinned. The other eight radii are fitted in closely, each one between two of the former, so that their lower ends come down on the corners of the octagon. The limb of the circle consists of two rings, the interior one having its plane parallel, and the exterior perpendicular, to the plane of the circle, so that, when united, their section

Practical Astronomy

will be represented by the letter T. The interior or flat ring has in the engraving the appearance of passing through clefts in the middle of the outer ends of the sixteen radii, which are there solid. The perpendicular ring is fitted close on the exterior edge of the other, to which it is screwed, and also to the ends of the conical radii. The cones are bound together at half the distance from the double ring to the centre by a circle of interposed bracing bars. The circular aperture of the octagon is shut up by plates before and behind, which are fastened to the octagon by strong steel screws. The posterior plate has a large circular hole, and the anterior a smaller one, both truly wrought. Into these the axis of motion is fitted, and united to the octagon and circle by means of screws. The axis is a cone of brass nearly seven inches in diameter in front, but behind only half as much, and nearly four feet long; this works in a socket, which at each end receives it, and in which it fits with the greatest possible exactness. The two parts which fit the axis are soldered into a strong brass tube, larger than the tube of the axis, but nearly of the same shape. On the tube of the sockets in front is soldered a strong perforated plate or upright bearing-piece, at right angles to the axis, which nearly fills the semicylindrical aperture in the wall; and at the remote end is soldered a short cylinder, the use of which will be explained. It is there that the adjustments for placing the circle in the meridian, and for levelling the axis, are performed. Two strong horizontal plates are fastened on the lower surface (which is flat) of the perforation through the wall, one before and the other behind. The bearing piece of the socket in front only rests upon the plate, but behind the bearing cock and plate are screwed together. In front the plate and bearing piece are connected by a conical piece of hardened steel, which is fixed under the middle of this piece, and fits nicely into a hole in the plate, but so as to revolve. At this end of the axis these parts do not come quite in contact; for there are fixed under the bearing piece, at each extremity, about ten inches apart, two short props, like buttons of hardened steel, the spherical surfaces of which rest upon planes of hardened steel fixed in the plate. The central conical piece prevents the circle from sliding sideways when angular motion is given round this conical piece to bring the instrument into the plane of the meridian. It has been stated that a short cylinder was soldered on the remote end of the cone of the sockets. This passes into a perforation in the cock behind, which perforation is greater than that of the cylinder. Two fine-threaded screws at right angles to each other work in the cock, one vertically for levelling, and the other horizontally for meridian adjustment. The two screws only press with their points against the sides of the short cylinder; but opposite to them are the ends of two small cylinders standing in the same line, which are urged forward with spiral springs, and thus force the short cylinders into contact with the screws. The telescope is seen on the face of the instrument; its focal length is six feet two inches, which is the exact outer diameter of the circle; the aperture is four inches, and its common magnifying power about 150. The telescope is attached to the circle at the centre by a steel axis, which passes through the proper axis of motion from end to end, and was indeed the arbor on which the axis was turned. The weight of the telescope is supported on its own axis, and it may be fixed to the circle in any position by means of two clamps which keep hold of the border of the circle. The graduation of the instrument is on the convex cylindrical surface of the exterior ring, therefore the reading microscopes have their direction parallel to the plane of the instrument. The divisions on Troughton's circle are made on a narrow ring of white metal composed of four parts gold to one of palladium; and the figures which count the degrees are engraved on a like ring of platina. In Jones's circle the divisions are on gold. None of these metals tarnishes in the least degree. The divisions are by lines, and suited to wires which cross at an acute angle in the reading microscopes. The degrees are cut into 5′ spaces, and are numbered from the pole southward to the same pole again, viz. from 0° to 360°. The 5′ spaces are subdivided by the microscopes to single seconds; and a division representing this quantity on the micrometer head may be easily estimated to the tenth of a second. There are six reading microscopes; which, during Mr Airy's direction, were always used.

Practical Astronomy

In order that the circle may move easily round on its axis, there is an apparatus for counterpoising it, or for lifting the whole weight, without which the load would press altogether on the lower side of the front socket. This is effected by means of two large rollers, shown below the axis in fig. 1. The rollers, set in a double frame, act on the edge of the centre flanch, nearly in contact with the radial cones. Two perpendicular bars of steel, at about the height of the centre, are connected with the frame of the rollers by hook and eye; and these bars are in a similar manner suspended by two beams, each resembling a common balance, at the top of the wall. The part which appears in front is shown in fig. 1, and one of the beams, its fulcrum and counterpoising weight, near the top of the wall, in fig. 2. This apparatus produces a simple lift, without any tendency to affect the due motion of the circle's axis.

There is another flat, circular ring, somewhat larger than the graduated one, fastened at several places to the wall, and nearly touching it. On this ring the clamp and screw for slow motion slide, and may be clamped to it at any part of the ring.

The plumb-line of the mural circle, seen in fig. 2, is for placing the axis truly horizontal. The apparatus by which the plummet is suspended was applied by dovetail fittings occasionally to the wall near its top, see fig. 1. The apparatus itself is shown in fig. 2. In fig. 1 fixed microscopes are seen on the telescope, near its end, for viewing the plumb-line.

The wires of the telescope are illuminated by a diagonal reflecting plate in the middle of the tube, which receives the light by a circular aperture, seen in fig. 1, in a line with the centre of the circle. A lantern, at four or five feet distance, placed in the line of the axis, throws light on the field of view.

The instrument seen in a vertical position on the back of the wall is a zenith tube. It was erected to discover, if possible, the parallax of a star that passes very near the zenith; but was never used.

The mural circle has as an accompaniment a clock; and since all observations made with it require to be corrected for refraction, which depends on the state of the atmosphere (see table in page 148), every recorded observation must have annexed to it the height of the barometer and thermometer.

We have now described the instruments which constitute the principal furniture of an observatory, and which are all that the present state of the science absolutely requires. We proceed next to describe some others which are extremely convenient, and almost equally necessary in the science.

6. *Equatorial Instruments.*

An equatorial instrument is of great value to a practical astronomer, for by means of it he can direct his telescope at once to any object, however minute, whose right ascension and declination are known; and conversely, he can determine the right ascension and declination of any object to which it is directed, although out of the meridian.

Plates XCV. and XCVI. give a representation of Sir James South's five-foot equatorial instrument. The greater part of this instrument is composed of tinned iron plate; and

Practical Astronomy

its characteristics are lightness, steadiness, promptness in answering to its adjustments, and capability of retaining them. Fig. 1 of Plate XCV. represents the instrument as viewed at right angles to the declination circle. The polar axis is about 10½ feet long; the lower end is a pivot attached to a cone, which, reckoning upwards, is about a fourth of the whole length. The higher side of the cone is cut in a sloping direction, as seen in the figure, for the purpose of more conveniently observing the vicinity of the pole. From the upper end of the cone the polar axis branches into two parts, between which is room for the declination circle and the head of the observer. These two branches are again united at the top by an open frame of bell metal, represented in fig. 2, to which the upper pivot is attached. This frame, as well as the iron-work which composes it, is so contrived as to present the least possible surface to obstruct the telescope; for the same reason the pivot at the top of the telescope is made as small as possible, whilst that at the lower end is considerably larger. Both ends of the axis are supported on stones, the northern end rising within about four inches of the level of the declination circle, the rest of the support being of wrought iron. At the southern end the stone rises very little above the floor, but a cast-iron frame supports the pivot at the height of about two feet. The Y, or angle which supports the lower pivot, is placed upon the frame, and provided with two screw adjustments, one for giving the axis its due elevation, and the other for bringing the instrument to the meridian. The form of the iron-work will be understood by consulting the different figures. The two branches of the polar axis on their upper sides are formed of broad planes, making one continued plane. On these the axis and reading microscopes of the declination circle are fixed. The instrument is self-balanced by the position and figure of its parts, and the addition of a weight fixed to the conical part of the polar axis. The diameter of the declination circle is four feet, the length of the telescope five feet, and of the axis about thirty-two inches. In Plate XCV. fig. 1, the declination circle appears quite plain, like the head of a drum with the telescope directed towards the equator. In Plate XCVI. fig. 1, the polar axis is considerably fore-shortened, from the position of the draughtsman in making the drawing of the instrument. In this figure the edge of the declination circle is shown as a short cylinder, with the telescope protruding beyond it. In this figure, also, the shape of the declination axis, and the two principal microscopes for reading the declination, are shown. There is a third microscope, which indicates zenith distances. This is seen in Plate XCV. fig. 1, between the eye end of the telescope and the instrument's elevated pole. In the same figure is shown a narrow brass ring, whereon the graduation is made.

The hour-circle, two feet in diameter, is fastened to the lower end of the polar axis; its edge is seen in Plate XCV. fig. 1, and its under side in Plate XCVI. fig. 1 and fig. 3. One of the reading microscopes is well seen in fig. 1 of Plate XCV., and both of them less perfectly in the other two figures. The circle is of brass, and the divisions (fine lines) are on an inlaid ring of platina, corresponding to twenty seconds each; these are subdivided by the microscopes to tenths of seconds. The declination circle is divided to spaces of five minutes, which are subdivided by the micrometer screw of the microscopes to single seconds. The instrument is furnished with two ground levels. The divided side of the declination circle is quite flat; but the opposite face is articulated, showing how the parts are united. It is on this side that the levels would be seen; one of them is parallel to the telescope, and the other to the declination axis.

Practical Astronomy

The clamps and screws for slow motion are unusual, but remarkably good. Instead of the common mode of clamping the circle, in this instrument the clamp is made to grasp the axis. There is soldered on each axis a ring of brass, the outer edge of which is broad and cylindrical. On this fixed ring a moveable one is fitted, and afterwards cut into three equal parts: these are again united in two of the three sections by joints, like those which bind the different parts of a watch chain together. At the third juncture the clamping takes place, a projecting part of the ring having been there cut through, leaving one half on each side of the section. Here the ring gapes, but a screw passes through the projecting pieces or ears on each side of the disjunction, and in bringing them together, grasps the axis with a firm embrace. To the middle of the tripartite rings are attached long arms of tinned iron plate, at the extremities of which the slow-moving screws have their places. The fixed stud is in the lower screw, planted in the iron support; that of the upper one is in the polar axis. The long screw for slow motion in right ascension is acted on by a contrate wheel and a pinion at right angles to the plane of the circle, as shown in fig. 1, Plate XCV.; a long handle is attached to it, and shown leaning against the northern pier. A similar screw for declination, but without the contrate part, is seen in Plate XCVI. fig. 1.

The illumination of the wires of the telescope is made by a small lantern placed at one end of the declination axis; and there is a contrivance between the nozzle of the lantern and the end of the axis, by which the light is adapted to different observations.

The eye-piece of the telescope is represented in Plate XCVI. fig. 2, in which there is seen the edge of a graduated circle, the front of a quadrant, and two small spirit-levels. There is likewise shown, but partially, a double parallel line micrometer, which also measures angles of position.

This instrument, when first constructed, was designed to be placed where a meridian mark could not be obtained. A mark, however, could be placed and seen to the westward; and to take advantage of this, the axis of the declination circle was converted into a telescope with two object-glasses of equal focus, two sets of cross wires, and an eye-glass that might be placed in either end; a mark was then built up to the level of the axis, and in a line at right angles with the meridian, and this formed a substitute for a meridian mark. The instrument bears no maker's name, but the scheme of its fabric was devised by the late Captain Huddart, F.R.S. The brass-work, &c., was made by J. and E. Troughton, under his direction; and the object-glass for the telescope of 3¾ inches aperture by P. and J. Dollond. To preserve the tinned work from oxidation, it is well covered with white paint, and varnished; thus it has not only a neat appearance, but can be easily cleaned at any time.

With this instrument, and another equatorial of seven-feet focal length, the object-glass being made by Tulley, Sir James South and Sir John Herschel made observations on the apparent distances and positions of 380 double stars; a work of which we have had occasion previously to make mention. (W. W.) (T. H.) (R. M—N.)

Astruc || Asturias.

ASTRUC, JEAN, a celebrated physician, born in 1684 at Sauves, in Languedoc. His father, a Protestant clergyman, bestowed particular pains upon his early education; after which he studied at the university of Montpellier, where, having commenced the study of medicine, he took his degree as doctor of physic in 1703. He now applied to the study of medical authors, both ancient and modern, with uncommon assiduity, and in 1710 published a treatise on muscular motion, from which he acquired very high reputation. In that year he was appointed to the chair of anatomy at Toulouse. In 1717 he was appointed to teach medicine at Montpellier. Rising rapidly into fame, he was successively appointed superintendent of the mineral waters of Languedoc; first physician to the king of Poland; and, in 1731, regius professor of medicine at Paris. Here he taught the practice of physic with so great applause, as to draw students from other universities, and from foreign countries. He was not more celebrated as a professor than a practitioner. Even at an advanced age he prosecuted his studies with unwearied assiduity; and was thus enabled to transmit to posterity so many valuable monuments of his medical erudition. He died on the 5th of May 1766, in the 82d year of his age.

Of his numerous works, that on which his fame principally rests, is the treatise entitled *De Morbis Venereis, libri sex*, 1736. 4to; afterwards enlarged to 2 vols. 4to, and translated into French by Jault, 4 vols. 12mo. Besides these, he published some treatises not connected with medicine, one with the title of *Conjectures sur les Memoires originaux qui ont servi à Moise pour ecrire la Genèse*, Bruxelles (Paris), 1753, 12mo; and two dissertations on the Immateriality, Immortality, and Liberty of the Soul, Paris, 1755.

ASTURIAS, one of the ancient provinces of the Spanish monarchy, distinguished by the title of a principality, and under that name conferred on the heir apparent to the throne of Spain. By the new division of Spain, however, in 1833, the old province of Asturias took the name of Oviedo. It is bounded on the N. by the Bay of Biscay, on the S. by Leon, on the W. by Galicia, and on the E. by Santander. This part of Spain was known to the Romans by the name of the Ultramontane provinces, being bounded on every side but the N. by high mountains, which are passable with difficulty by horses, and nearly impassable by wheel-carriages. The principal road through the province is the *Camino real* or royal highway from Gijon and Leon to Madrid. This magnificent road, which cost so much that Charles IV. inquired if it were paved with silver, is carried by means of bridges and embankments over every impediment of a rugged and mountainous territory. In winter, however, it is in some places almost impassable. A railroad is now in progress from Aviles to Madrid, through Leon and Oviedo. Asturias contains 3460 square miles, and its population in 1849 amounted to 510,000. It is divided into 77 *audiencias*, which vary greatly as to their extent and productions. The face of the country is excessively irregular and mountainous; the higher elevations are not cultivated; and even in the valleys, which are irrigated by numberless streams, though there is abundant pasture for cattle, there is a great deficiency of corn. The flour of maize constitutes the principal food of all but the higher classes of inhabitants. Wheat is not much grown. The humidity weakens the plant; and though at first it appears to flourish, and looks well till it is in blossom, the crop frequently fails. Rye grows better, and constitutes part of the food, especially when mixed with maize. Chesnuts, as elsewhere in Spain, form an important part of the sustenance of the inhabitants. They are very abundant on the hills, and the nuts as well as the wood are very valuable products. Other kinds of timber well calculated for shipbuilding are found in the mountains; and several medicinal plants, such as hellebore, valerian, angelica, and others, which form trifling branches of commerce. Cows and horses are reared in this province, and considerable numbers of them are sent to Galicia, Leon, and the two Castiles. Vines, for want of due attention, do not flourish. Very little wine is made, and that little of bad quality; but to compensate for this deficiency, there is abundance of apples, and cider forms the common drink of the people. In some parts of the province there are very valuable mines of coal, some of which is transported to Cadiz, Carthagena, and other ports in the Mediterranean. The quantity yielded in 1847 was 472,000 quintals, being three times the amount in 1835. In the lower parts of the country, especially on the sea-coast, at a distance from coal-mines and forests, the inhabitants use turf or peat for firing. In the vicinity of the river Aviles, some mines of copper and iron are worked. The other mineral productions are gold, lead, zinc, magnesia, arsenic, cobalt, lapis-lazuli, alum, antimony, jet, marble, and rock-crystal. Fuel being plentiful, several manufactories of copper utensils have been established, which supply some parts of Leon and Castile with braziers' kettles, pots, and other similar articles. Besides these, there is a royal manufactory near Oviedo, where, in blast-furnaces, cannon-balls, grenades, bombs, and cannon of all calibres are cast. Some coarse cloths are made, but not sufficient to supply the inhabitants. Asturias.

The province is generally mountainous, especially in the S., where it is intersected by numerous ramifications of the Pyrenees. These gradually decline in height as they approach the ocean, along the border of which is a narrow stripe of the best and most populous portion of the principality. From the narrowness of this tract, it must be seen that the courses of all the rivers are necessarily short and rapid, and that they are very apt to overflow the country when the rains descend on the mountains. The Nalon, its principal river, passes the city of Oviedo, before which it receives the river Caudal, formed by the junction of two others, namely the Pola de Leon and the Aller. After passing Oviedo, the rivers Trubia and Narcea contribute their streams, when, after a course of 62 miles, it falls into the ocean. Along the whole extent of the coast of Asturias, a distance of 130 miles, there is not one good port. In that of Ribadesella, a large frigate may anchor; but it is difficult of access. Gijon will admit a vessel drawing 16 or 17 feet water, but the entrance here is also very narrow and dangerous. The principal city of the province is Oviedo. (See OVIEDO.) At a league from the city are the warm baths of Caldas. The spring issues from a calcareous rock of secondary formation: it is much resorted to, being found highly beneficial in many diseases. Gijon is honoured by having been the native place of Jovellanos, one of the wisest and best men that Spain has recently produced. He founded here the Asturian Institution, destined for the instruction of youth in mathematics, mineralogy, and navigation, which continues to flourish, though the building is still unfinished. He also projected the road for wheel-carriages from Gijon to Leon. The cabildo of Oviedo has done honour to his memory by erecting at the gate of their city, through which this road passes, a stone with an inscription to perpetuate the obligations which his country owes to him. At 10 leagues to the E.S.E. of Oviedo stands the collegial church and sanctuary of Covadonga, famous in the history of the period when the remains of the Goths were collected in the mountains of Asturias, and commenced that struggle against the Moors which continued during seven centuries, till the last of that wonderful people were finally driven out of the peninsula. The sea-coasts, as well as the small rapid streams, abound with fish of various kinds, the latter especially with salmon and lampreys, which are sent to supply the markets of Madrid. The Asturians are principally employed in agriculture. Their character is marked by the qualities which generally distinguish the inhabitants of mountainous regions; and they have been called the Swiss of Spain. They are robust, patient, and hardy; unenterprising but laborious; hospitable to strangers, and enthusiastic lovers of their country. Naturally prone to meditation, their imaginative spirit delights to dwell on

Astyages || Asymmetry.

the romantic traditions of the past, which their mountain-homes on every side call to remembrance. Among all the inhabitants of Spain they hold the first place in the comparative scale of morals, as is shown by the fact that in the province of Oviedo the proportion of crimes to the number of inhabitants is as 1 to 898, while in Madrid it is as 1 to 137. Their idiomatic dialect, called *Bable*, has suffered little changes since the days of Alonso X.; preserving more of the primitive type than the other dialects derived from the Latin. The important events of the early history of this principality will be found under the article SPAIN.—*Historia Natural de Asturias*, por Don Mariano Lagasca; *Viage de Ponz; Geografia de España*, por Antillon; Madoz, *Diccionario Geographico de España;* Ford's *Handbook of Spain.*

ASTYAGES, son of Cyaxares, and the last king of Media, began to reign in the year 594 B.C., and was dethroned by his grandson Cyrus, B.C. 559. Herodotus and Xenophon differ materially in the relation of this story: according to the latter, Cyrus peaceably succeeded to the throne on the death of Cyaxares II., the son of Astyages. See CYRUS.

ASTYANAX or SCAMANDRIUS, was the only son of Hector and Andromache. After the taking of Troy he was thrown headlong from a tower by order of Ulysses.

ASTYNOMI (ἀστυνόμοι), in *Grecian Antiquity*, magistrates in Athens, corresponding to the ædiles of the Romans. They were ten in number.

ASYLUM, a sanctuary or place of refuge where criminals shelter themselves from the hands of justice. The word is compounded of the privative particle α, and σύλη, *violence;* because no person could be taken out of an asylum without sacrilege. The asyla of altars and temples were very ancient, and likewise those of tombs, statues, and other monuments of distinguished personages. Thus, the temple of Diana at Ephesus was a refuge for debtors, the Theseium at Athens for slaves. At Rome a celebrated asylum was opened by Romulus between the mounts Palatine and Capitoline, for all sorts of persons indiscriminately, fugitive slaves, debtors, and criminals of every kind, in order to people the city. The Jews had their asyla, the most remarkable of which were the six cities of refuge, the temple, and the altar of burnt-offerings. It was customary among the heathens to allow refuge and impunity even to the vilest and most flagrant offenders; some out of superstition, and others for the sake of peopling their cities. We even read of asylums at Lyons and Vienne among the ancient Gauls; and there are some cities in Germany which still preserve the ancient right of asylum. Hence, on the medals of several ancient cities, particularly in Syria, we meet with the inscription ΑΣΥΛΟΙ, to which is added ΕΡΑΙ. This quality of asylum was given them, according to M. Spanheim, in regard to their temples, and to the gods revered by them. The Emperors Honorius and Theodosius granting the like immunities to churches, the bishops and monks laid hold of a certain tract or territory, without which they fixed the bounds of the secular jurisdiction; and so well did they manage their privileges, that convents in a little time became the next thing to fortresses, where the most notorious villains braved in safety the power of the magistrate. These privileges were extended not only to the churches and churchyards, but also to the bishops' houses, whence the criminal could not be removed without a legal assurance of life, and an entire remission of the crime. The reason of the extension was, that they might not be obliged to live altogether in the churches, &c., where several of the occasions of life could not be decently performed. But at length these asyla or sanctuaries were also stripped of most of their immunities, because they served to make guilt and libertinism more bold and daring. In England, particularly, they were entirely abolished. See SANCTUARY.

ASYMMETRY, the want of proportion between the parts of anything; being the contrary of *symmetry*. Or, it is the relation of two quantities which have no common measure, as 1 and $\sqrt{2}$, or the side and diagonal of a square.

Asymptote || Ath.

ASYMPTOTE, in *Geometry*, a line which continually approaches nearer to some curve, but which, though continued infinitely, would never meet it. This property belongs to the hyperbolic curve and its asymptotes, which are in relation to each other as a repeating decimal fraction and unity. The term is derived from the Greek ἀσύμπτωτος (from α, priv., σύν and πίπτω), "not falling together."

ASYNDETON (α and συνδέω, to *bind*), in *Grammar*, a figure which omits the conjunctions in a sentence; as in *veni, vidi, vici*, where ET is left out; or in that of Cicero concerning Catiline, *abiit, excessit, evasit, erupit.*

ATACAMA, a division of Bolivia in South America, remarkable for a vast desert tract along the Pacific.

ATACAMITE, a mineral found in that desert in some quantity. It is an oxychloride of copper, of a rich green colour, massive, or pulverulent.

ATAHUALPA, the last of the Incas. See PERU.

ATALANTA, in *Grecian Fable*, the most swift-footed of mortals, promised her hand in marriage to him who should outstrip her in the race, on the condition, however, that the unsuccessful competitor should suffer the penalty of death. Milanion at length succeeded in obtaining her for his wife, by the stratagem of dropping during the race three golden apples, whose beauty so charmed Atalanta that she stopped to gather them, and thus suffered herself to be defeated. After their nuptials they were metamorphosed into lions for profaning a sanctuary by their embraces.

ATAMELIK, a learned native of Khorassan, who was a prefect of Baghdad under Hulaku, and author of a history of the Moguls, said to exist in MS. in the National Library at Paris. He was born in 1226. The period of his death is uncertain.—See *Mines de l'Orient*, vol. i.

ATCHAFALYA, a river of Louisiana, in North America, or more properly a secondary channel of the Mississippi, by which a portion of its waters flows off from the main trunk into the Mexican Gulf. Its mouth is 100 miles W. of the principal embouchure of the Mississippi.

ATE, in *Pagan Mythology*, the goddess of mischief. When Jupiter was deceived by Juno, after he had sworn to her that the next descendant of Perseus should reign over that race, his vengeance fell upon his daughter Ate, on the supposition that it was through her interference that Hercules was deprived of his heritage by the earlier birth of Eurystheus; whereupon she was hurled from Olympus, and banished for ever from the abodes of the celestials. In the tragic writers the character of Ate resembles that of Nemesis and Erinnys.

ATELLANÆ FABULÆ, in *Roman Antiquity*, a species of low comedy, invented by the people of Campania, and adopted by the Romans. They seem to have consisted of metrical effusions, in burlesque imitation of the manner and dialect of the peasantry, with satirical humour.

ATERGATIS, in *Mythology*, a goddess of the Syrians, supposed to be Derceto, the mother of Semiramis. She was represented with the face and breasts of a woman, but the rest of her body resembled a fish. It has been conjectured that she is perhaps the female counterpart to the *Dagon* of the Philistines.—See Lucian, *De Dea Syria.* xiv.; Diodorus, ii.

ATESTE, a town in Austrian Lombardy, now Este.

ATH, or AETH, a city of Belgium, province of Hainaut, situated on the river Dender. It is well built, and was strongly fortified by Vauban; has an arsenal, with several bomb-proof magazines; a church dedicated to St Julian, a town-house, college, school of design, orphan asylum, theatre, &c. It contained in 1850, exclusive of the garrison, 8437 inhabitants, chiefly employed in refining sugar and salt, in making soap, beer, and gin, and in the cotton and linen manufactures. It is 25 miles from Brussels. Long. 3. 46. 32. E. Lat. 50. 42. 17. N

Athabasca || Athanasius.

ATHABASCA, or ATHAPESCOW, a river in the north-western territory of British North America, which flows into a lake of the same name. It rises in the Rocky Mountains, and has a long and tortuous course in a north-eastern direction, during which it receives the Lesser Slave River, the Red Deer, and several others. The lake is about 230 miles in length, with a breadth varying from 30 to 14 miles, lying in a direction almost E. and W., in Lat. 59. N. Long. 110 W.

ATHALIAH, the daughter of Ahab and wife of Jehoram king of Judæa, who, after the death of King Ahaziah, her son, butchered all the seed-royal of the house of Judah, that she might usurp the throne. Among the victims were her own grandchildren, except the youngest, whom the affectionate pity of his aunt Jehosheba concealed in the Temple, where he was protected by the high priest Jehoiada for six years. At the end of that time the priest showed their infant king to the nobles, and exhorted them to put this infamous woman to death; which was promptly done, as soon as she was without the precincts of the Holy Place. The story of Athaliah forms the subject of one of Racine's best tragedies.

ATHANASIAN CREED, a formulary or confession of faith, long supposed to have been drawn up by Athanasius, bishop of Alexandria in the fourth century, to justify himself against the calumnies of his Arian enemies: but it is now generally admitted among the learned that he was not the author. Dr Waterland, in his *Critical History of the Athanasian Creed*, ascribes it to Hilary, bishop of Arles, for the following among other reasons:—1. Because Honoratus of Marseilles, the writer of his life, tells us that he composed an *Exposition of the Creed*—a more proper title for the *Athanasian* than that of *Creed* simply, which it now bears. 2. Hilary was a great admirer and follower of St Austin; and the whole composition of this creed is in a manner upon St Austin's plan, both with respect to the Trinity and incarnation. 3. It is agreeable to the style of Hilary, as far as we can judge from the little that is left of his works. Upon the whole, he concludes that Hilary, bishop of Arles, about the year 430, composed the *Exposition of Faith* which now bears the name of the *Athanasian Creed*, for the use of the Gallican clergy, and particularly those of the diocese of Arles; that about the year 570, it became famous enough to be commented upon; but that all this while, and for several years longer, it had not yet acquired the name of *Athanasian*, but was simply styled *The Catholic Faith*; that before 679 Athanasius's admired name came in to recommend it, being in itself an excellent system of the Athanasian principles of the Trinity and incarnation, in opposition chiefly to the Arians, Macedonians, and Apollinarians. This creed was received in France in the time of Hincmar, or about 850; in Spain and Germany about 100 years later. We have clear proofs of its having been sung alternately in our churches in the tenth century. It was in common use in some parts of Italy, particularly in the diocese of Verona, about the year 960, and was received at Rome about the year 1014. It has been questioned whether any of the Greek and oriental churches ever received this creed at all, though some writers of authority are of a contrary opinion. It appears, then, that the reception of this creed has been both general and ancient, and that it may vie with any in that respect, except the Nicene or Constantinopolitan, the only general creed common to all the churches. As to its matter, it is given as a summary of the true orthodox faith, and a condemnation of all heresies, ancient and modern. Unhappily, however, it has proved a fruitful source of unprofitable controversy and unchristian animosity.

ATHANASIUS, ST., bishop of Alexandria, and one of the greatest defenders of the faith against the Arians, was born at Alexandria in Egypt, about the year 296. He followed St Alexander to the Council of Nice in 325, where he disputed against Arius, and the following year was made bishop of Alexandria. In 335 he was deposed by the council of Tyre; when, having recourse to the Emperor Constantine, the Arian deputies accused him of having hindered the exportation of corn from Alexandria to Constantinople; on which the emperor, without suffering him to make his defence, banished him to Treves. The emperor, two years after, gave orders that he should be restored to his bishopric; but, on his return to Alexandria, his enemies brought fresh accusations against him, and chose Gregory of Cappadocia to his see, which obliged Athanasius to go to Rome to reclaim it of Pope Julius. He was there declared innocent, in a council held in 342, and in that of Sardica in 347, and two years after was restored to his see by order of the Emperor Constans; but after the death of that prince he was again banished by the Emperor Constantius, which obliged him to retire into the deserts. The Arians then elected in his stead one George, who was killed in a popular sedition under Julian in 360. St Athanasius then returned to Alexandria, but was again banished under Julian. His successor Jovian, however, being a Christian, restored him to his see. To that emperor he addressed a letter, in which he proposed that the Nicene creed should be the standard of the orthodox faith, and condemned those who denied the divinity of the Holy Ghost. He was afterwards banished by Valens in 367, but again returned from what has been termed his fifth exile. He died in 373. His works principally contain a defence of the mysteries of the Trinity, and of the incarnation and divinity of the Word and Holy Spirit. There are three editions of them which are esteemed: that of Commelin, printed in 1600; that of Peter Nannius, in 1627; and that of Father Montfaucon. The most complete edition, however, is that published at Padua in 1777, in four vols. folio. As to the creed which bears the name of Athanasius, see the preceding article.

Athanati || Athelingey.

ATHANATI, (*ἀθάνατοι, immortals*), in *Persian Antiquity*, a body of cavalry, consisting of 10,000 men, always complete. They were called *athanati*, because when one of them happened to die another was immediately appointed to succeed him.

ATHANERIK, a valiant leader of the Visigoths, who, though defeated once by the generals of the Emperor Valens in 369, was afterwards raised to the head of his nation, and when he died in 381, left behind him a reputation for fortitude and sagacity.—*Ammianus; Gibbon.*

ATHEIST (from *α*, priv., and Θεὸς, God), one who denies or disbelieves the existence of a Deity. Many, both ancient and modern, have pretended to atheism, or have been reckoned atheists by the world; but it may justly be questioned whether any man ever seriously adopted such a principle. Vulgar prejudice and bigotry also, from the time of Socrates downwards, have frequently fastened the charge of atheism where it was least of all appropriate. Among us, the greatest philosophers have been the principal advocates for the existence of a Deity. So true is the saying of Lord Bacon, that though a smattering of philosophy may lead a man into atheism, a deep draught will certainly bring him back again to the belief of a God and providence.—See Reimann's *Historia Atheismi*, &c., 8vo, Hildesh. 1725; and Sylvain Maréchal's *Dictionnaire des Athées*, 8vo, Paris, 1799.

ATHELING, ADELING, EDELING, ETHLING, or ETHELING, among the Anglo-Saxons, was a title of honour, properly belonging to the heir-apparent or presumptive to the crown. It was first conferred by King Edward the Confessor on Edgar, to whom he was great uncle, when, having no issue of his own, he intended to make him his heir.

ATHELINGEY, or NOBLES' ISLAND, a fastness in Somersetshire, in which King Alfred concealed himself when the Danes overran his country. It is now a gentle eminence in a cultivated district; it was then a jungle of about 100 acres, surrounded by a deep morass, from which he issued in many successful assaults on his astonished enemies.

Athelstan ‖ Athens.

It is commonly called Athelney, and is now occupied by a single farm-house.

ATHELSTAN, a Saxon king of England, natural son of Edward the Elder, and grandson of the great Alfred. He succeeded to the crown in 925, and reigned 16 years. A remarkable law passed by this prince, shows his just sentiments of the advantages of commerce, as well as the early attention to it in this country: it declared that any merchant who made three voyages on his own account beyond the British channel or narrow seas should be entitled to the privilege of a thane or gentleman.

ATHENÆUM (*Ἀθήναιον*), in *Antiquity*, a public place in which the professors of the liberal arts held their assemblies and gave instruction, the rhetoricians declaimed, and the poets rehearsed their performances. The three most celebrated Athenæa were those at Athens, at Rome, and at Lyons; the second of which was built by the Emperor Hadrian, and continued in high repute till the fifth century. The name Athenæum is frequently applied in modern times to establishments connected with literature and art, to public libraries, and the like.

ATHENÆUS, a mechanician of Magna Græcia, who dedicated to Marcellus, the conqueror of Syracuse, a work termed Περὶ Μηχανημάτων, "On Warlike Engines." It is extant in Thevenot's *Mathematici Veteres*. He must have flourished about the year 214 B.C.

ATHENÆUS, a physician of Attalia in Asia Minor, the founder of the *Pneumatic* sect, in the first century. Some of his opinions are preserved in Aetius, Oribasius, and Galen, from which it would appear that he attributed the movements of the heart and the pulse to a *fifth element*, Πνεῦμα; and therefore it would seem that he held the doctrine of a *vital principle*.—Le Clerc, *Hist. de la Medicine*.

ATHENÆUS, a Greek grammarian of great erudition, was a native of Naucratis in Egypt, and lived about A.D. 230, first at Alexandria, and afterwards at Rome. The only one of his works extant is that entitled *Deipnosophistæ* (Δειπνοσοφισταί), or *Banquet of the Learned*, in 15 books, of which the first two, and parts of the 3d, 11th, and 15th, exist only in epitome. This work is an almost inexhaustible store of anecdotes, facts, quotations, criticisms, and discussions, on subjects of the most diversified kind; and it is valuable for the light it throws on many curious circumstances regarding the ancients. Editions: by Aldus, Venice, 1514; Casaubon, Geneva, 1597; Schweighaüser, Strasbourg, 14 vols. 8vo, 1801–7; W. Dindorf, 3 vols. 8vo, Lips. 1827, which is the best. There is also a French translation in 5 vols. 4to, by M. Lefevre de Villbrune.

Athenagoras ‖ Athens.

ATHENAGORAS, an Athenian philosopher who flourished about the middle of the second century. Originally a disciple of Plato, he embraced Christianity, and distinguished himself by the zeal and learning which he brought to its defence. Two of his works are extant—an *Apology for Christianity*, addressed to the Emperors Marcus Aurelius Antoninus and Lucius Commodus, and a *Treatise on the Resurrection*. The best edition of his works is that of the Benedictines, published at Paris in 1742, together with the writings of Justin Martyr, Theophilus of Antioch, and Hermias, in one vol. folio. There is also an English translation by Humphreys, London, 1714.

ATHENODORUS, surnamed CANANITES or SANDONUS, a Stoic philosopher, was born at Tarsus, and went to the court of Augustus, who made him tutor to Tiberius. Augustus esteemed him greatly, having proved by experience his virtue and probity. He used to speak very freely to the emperor, and warned him, whenever he found himself giving way to anger, to rehearse the twenty-four letters of the alphabet before he resolved to say or do anything. He died at the age of 82. None of his works have survived. There was another Stoic of this name, surnamed *Cordylion*, also of Tarsus, who was keeper of the library at Pergamus, and died at Rome in the house of Cato the Younger. There were likewise two sculptors named Athenodorus, one of whom assisted Agesander in the group of the Laocoon.

ATHENRY, a decayed town of Ireland, county of Galway, and province of Connaught, 14 miles E. of Galway. It is a place of antiquity, and traces of its walls, castle, and an old Dominican friary, are still visible. From the time of Richard II. till the Union it returned two members to parliament. Pop. in 1851, 1487.

ATHENS.[1]

ATHENS (Ἀθῆναι, *Athenæ*), "the eye of Greece" (to use Byron's phrase), the capital of Attica, and the birthplace of the most distinguished poets, orators, philosophers, statesmen, historians, and artists of antiquity, is situated in Long. 23. 44. E. Lat. 37. 58. N., in the central plain of Attica, about four miles from the coast. See ATTICA. The city of Athens consisted of three distinct parts: 1. The town on the rock, or the Acropolis, also simply called ἡ πόλις; 2. The city of Athens below and around the Acropolis, generally called τὸ ἄστυ; and sometimes ἡ κάτω πόλις, or lower city; and 3. The port towns, including Peiræus, Munychia, and Phalerum.

By whom founded.

The origin of Athens, like that of most other ancient and renowned cities, is involved in the obscurity of fable. Its reputed founder was Cecrops, an Egyptian, who brought from Sais the worship of the goddess Neith, called by the Athenians Ἀθήνη, and who, in the opinion of the learned, was contemporary with Moses. The new city was built on the rock of the Acropolis, which originally contained all the habitations of the Athenians, and received from Cecrops the name of Cecropia. But in the time of Erechtheus, called by later writers Erichthonius, the second of the early kings in succession from Cecrops, and the person who is said to have instituted the festivals called *Athenæa*, in honour of Ἀθήνη or Minerva, it lost the name which it had derived from its founder, and acquired that of Ἀθῆναι, *Athens*, from the goddess to whose worship it was principally dedicated.

Ancient state.

We have received little or no information respecting the size or dimensions of Athens under its earliest kings. It is generally supposed, however, that even as late as the time

[1] The principal works on the Topography of Athens, which has been discussed at length, and with great accuracy and research, by modern antiquaries and travellers, are Stuart's *Antiquities of Athens*; Dodwell's *Classical Tour*, vol. i.; Mr Hawkins' *Dissertation on the Topography of Athens* in Walpole's *Memoirs*, vol. i. p. 480; Colonel Leake's *Topography of Athens, with some Remarks on its Antiquities*; P. W. Forchhammer's *Topographie von Athen*, Kiel, 1841, 8vo; Wordsworth's *Athens and Attica*, London, 1836; and Mr Cramer's *Geographical and Historical Description of Ancient Greece*, vol. ii. p. 309. These writers, with the exception of Mr Cramer, have in general followed Pausanias, who, having himself visited Athens, describes, in his first book, its antiquities and most remarkable edifices. But as it is admitted on all hands that Pausanias has neglected to notice several important buildings pointed out by other authors, and that his description is, besides, defective in several particulars, we have availed ourselves of the additional information supplied by Meursius in his *Athenæ Atticæ*, and by succeeding antiquaries, in order that we might be enabled to form as accurate a list as possible of the principal edifices and monuments of this celebrated city.

Athens.

ot Theseus the town was almost entirely confined to the Acropolis and the adjoining hill of Ares or Mars. But during the six or seven centuries which elapsed between the Trojan war and the reign of Peisistratus, it appears to have increased considerably both in extent and population;[1] while the adminstration of that enlightened and patriotic usurper, so far from proving an impediment to the prosperity of the city, operated in aid of its improvement; as has often happened when power chances to fall into the hands of a person of taste and munificence. By establishing a public library, and by editing the works of Homer, Peisistratus and his sons fixed the Muses at Athens. Nor in the midst of all this attention to the cultivation of the arts and the embellishment of the city, had the means of defence against external aggression been neglected. For, since Athens was able to withstand a siege by the Lacedæmonians, during the reign of Hippias, one of the sons of Peisistratus, we may conclude that it already possessed walls and fortifications of sufficient height and strength to ensure its safety.

Effects of the Persian invasion.

But the invasion of Xerxes, and the subsequent irruption of Mardonius, effected the entire destruction of the ancient city, and reduced it to a heap of ruins; with the exception only of such temples and buildings as, from the solidity of their structure, were enabled to resist the action of fire and the work of demolition. During their temporary ascendancy in Greece, the Persians displayed the same iconoclastic fury which had marked their career of conquest in Egypt with havoc and desolation. But when the battles of Marathon, Salamis, Platæa, and Mycale, had dissipated the forces of the invader, and liberated Greece from the danger of subjugation to a foreign power, Athens, restored to peace and security, soon rose out of its ruins with increased splendour; and having been provided by Themistocles with the military works necessary for its defence, it attained, under the subsequent administrations of Cimon and Pericles, to the highest pitch of beauty, strength, and magnificence. The former, indeed, is known to have erected the temple of Theseus, the Dionysiac Theatre, the Stoæ, and the Gymnasium, and also to have embellished the Academy, the Agora, and other parts of the city, at his own expense;[2] while the latter completed the fortifications which had been left in an unfinished state by Themistocles and Cimon—rebuilt several edifices which the Persians had destroyed—and, above all, immortalized himself by the construction of the temple of Eleusis, the Parthenon, and the Propylæa, edifices unrivalled alike for classical purity of design and perfection of execution.

Age of Pericles; population.

It was, indeed, under the administration of Pericles that Athens attained to that eminence in art which has excited the wonder and admiration of all succeeding ages: it was to this illustrious man that the city was principally indebted for the splendour of its architectural decorations, and the republic for its prosperity and its power. At the period in question the whole of Athens, with its three ports of Peiræus, Munychia, and Phalerum, connected by means of the celebrated Long Walls, formed one great city, inclosed within a vast peribolos of massive fortifications, extending to not less than 174 stadia, of which the circuit of the city amounted to 43, the long walls taken together to 75, and the circumference of the three harbours to 56.[3] There is some difficulty in ascertaining the amount of the population of Athens at this period. Xenophon informs us that it contained more than 10,000 houses, which, at the rate of ten persons to a house, would give 100,000 souls for the whole population of the city. By a census of Pericles, mentioned by Plutarch in his life of that statesman, it, however, appears that the number of Athenians entitled to exercise the rights of citizenship was confined to 14,040; and at no subsequent period does this number appear to have much exceeded 20,000, which indeed may be taken as the average amount of the free adult male population of Athens, enjoying the rights of citizenship. See ATTICA.

Athens.

Dimensions of the walls.

From the researches of Colonel Leake and others, it appears that the ancient city considerably exceeded in extent the modern town; for, although the scanty remains of the old fortifications are insufficient to enable us to judge of their circumference, it is nevertheless evident, from the measurement furnished by Thucydides, that they inclosed a much larger space than that contained within the present line of wall, particularly towards the north. It is probable, indeed, that, on this side, the extremity of the city reached as far as the foot of Mount Lycabettus; and that, to the westward, its walls followed the course of the small brook which terminates in the marshy ground of the Academy, until they met the point where some of the ancient foundations are still to be seen near the Dipylum; while, to the eastward, they approached close to the Ilissus, a little below the present church of the Mologitades or Confessors. The entire peribolos of the fortifications, including the walls of the city, the longimural inclosure, and the defences of the ports, cannot therefore have been less than 19 miles; but from the extreme irregularity of the space inclosed, it is impossible to form any accurate estimate of its dimensions. Ancient writers inform us, however, that Athens was nearly equal in extent to Rome within the walls of Servius; and Plutarch compares it in point of size to Syracuse, which Strabo estimates at 180 stadia, or upwards of 22 miles in circumference.

Gates, Dipylum, &c.

The number of gates in the fortifications of ancient Athens is uncertain; but the names of nine have been preserved by the classical writers. These are Dipylum (otherwise called Ceramicæ), Diomeiæ, Diocharis, Melitides, Peiraicæ, Acharnicæ, Itoniæ, Hippades, and Heriææ. The Dipylum was situated in that part of the wall which separated the inner from the outer Ceramicus, and formed the communication between them; from which circumstance it was sometimes called the gate of Ceramicus. A little to the south of the Dipylum was the Sacred Gate, from its leading into the Sacred Way; also called the Thriasian gate, or gate of Thria, from its conducting to or forming the outlet in the direction of Eleusis and Megara. On the north-west side of the Acropolis, in a hollow adjoining a small church built on a rock and dedicated to St Athanasius, there still remain some appearances of the foundations of a gate; and here, accordingly, Colonel Leake and others have fixed the site of Dipylum. The Diomeiæ, probably so called from Diomeia, one of the Attic demi, which itself received its name from the hero Diomus, was nearly opposite the entrance of the suburban gymnasium called Cynosarges, a place dedicated to Hercules, and situated to the north-east of Athens. The gate of Diocharis fronted the entrance of the Lyceum, near to the fountain of Panops; while that called Melitides was situated in the southern part of the wall, towards the sea and Phalerum; and the Peiraicæ, as its name sufficiently implies, led to the harbour of the Peiræus. Traces still exist of the Melitides and Peiraicæ, as well as of the Dipylum.

---

[1] This must have been true even in the time of Homer, who applies to it the epithets of *εὐκτιμένη* and *εὐρυάγυια*, which seem to indicate a place of some consideration.

[2] Plutarch, *in Vit. Cimon.*

[3] Taking the itinerary stadium at 575 English feet, or the length resulting from the equation of 19 English miles with 174·5 stadia, it would of course follow that the peribolos of fortifications was just the same number of miles in extent. But it has been ascertained that the Greek stadium in the time of the Roman emperors exceeded the itinerary stadium by 30 feet, or, in other words, was equal to 605 English feet; which, taken as the true value of the measure, would consequently give 605×174÷5280=19·9375 miles as the entire circumference. (Leake's *Topography*, p. 369.)

Athens. There can be little doubt that the gate called Acharnicæ was so named from its leading to the demus of Acharnæ, the situation of which was probably at or near the modern village of Menidhi, close by the spot where the present road to that village intersects the line of the ancient walls. The site of the Itonian gate, mentioned in the dialogue of Axiochus, is placed by Colonel Leake about half-way between the Ilissus and the foot of the hill of Museum, where the road leading direct to Phalerum from the modern Inté-kapesi or Albanian gate cuts the line of the ancient walls. Of the Hippades we only know that it was the gate on the outside of which was the sepulchre of the family of the orator Hyperides. It seems to have derived its name from some equestrian statues erected near it; and it is not improbable that the Hippades may have been the gate between Dipylum and the Peiraic, of which some vestiges still exist on the north side of the Hill of Nymphs, commonly, but erroneously, called Mount Lycabettus. Lastly, the Heriæ or Heriææ was so called from its being the gate through which corpses were usually conveyed to the burying-ground, but its precise site cannot now be discovered. Athens, in fact, was surrounded on every side with an immense cemetery. On the north-west and north, from the northern long wall to Mount Lycabettus, generally but falsely called Anchesmus, there was a continued succession of sepulchres; and the excavations made in search of sepulchral antiquities have proved that there were similar burying-grounds on the outside of the southern long wall.[1]

Pompeium and temple of Ceres. Pausanias commences his description of Athens apparently from the Peiraic gate. We shall imitate his example, and follow nearly the same course; supplying his omissions as we go along, and conjoining with our accounts of ancient edifices and monuments notices of their existing state and condition where any traces or vestiges of them still remain. On entering the city, the first building remarked by Pausanias was the Pompeium. This was so called from its being the depository of the sacred vessels (*πομπεῖα*) used in certain processions, which, being of great value, had a separate building appropriated for their safe custody. In the Pompeium there was also a statue of Socrates by Lysippus, together with several portraits of eminent individuals, amongst which that of Isocrates has been particularly mentioned. Near this edifice stood a temple of Demeter (Ceres), containing statues of that goddess, of her daughter Persephone, and of Iacchus, executed by Praxiteles; and beyond it were several porticoes leading from the city gates to the outer Ceramicus; while the intervening space was occupied by some temples, the Gymnasium of Hermes, and the house of Polytion, where some Athenians of distinction (probably Alcibiades and his companions) are said to have celebrated mysteries similar to those of Eleusis.[2]

Ceramicus. There were two places in Athens known by the name of Ceramicus;[3] one without the walls, forming part of the suburbs; and the other within, including a considerable and very important section of the city. The outer Ceramicus was covered with the sepulchres of the Athenians who had been slain in battle, and buried at the public expense, with the exception of those who fell at Marathon, and who were interred on the spot where they had died so gloriously; and it appears to have communicated with the inner Ceramicus by means of the gate Dipylum, which is understood to be the Ceramic entrance alluded to by Philostratus. The Ceramicus *intra muros* probably included the Agora, the Stoa Basileios, and the Poecile, besides various other temples and public buildings. Antiquaries, it is true, are not decided as to the general extent and direction of this portion of the ancient city; but, from the researches and observations of Colonel Leake, it seems pretty certain that it lay entirely on the south side of the Acropolis,[4] where it was of course bounded by the city walls, which ran close to the fountain Callirrhoe, or Enneacrunus; and that, consequently, its breadth could not have exceeded one-half of its length.[5] We shall now give some account of the edifices in this part of the ancient city, reserving what we have to say of the outer Ceramicus until we come to describe the suburbs. Athens.

Ceramic edifices. The first building mentioned by Pausanias is the Stoa Basileios, so called because the archon basileus held his court there, and which probably stood at the western extremity of the Areiopagus. Its roof was adorned with statues of baked clay; and adjoining it were statues of Cimon, and Evagoras, king of Cyprus. Behind this portico was another, containing paintings of the twelve gods, and of Theseus and "the fierce democracy,"—thus implying that he was the first to establish equal rights among the citizens of Athens; together with a picture by Euphranor, representing the achievements of the Athenian auxiliary cavalry at the battle of Mantineia. The temple of Apollo Patrous was situated in the vicinity of the latter portico, and was dedicated to that god in his capacity of *Alexicacus*, that is, the averter of evil, such as the plague and other epidemics. The Metroum, a temple consecrated to the mother of the gods, was the grand depository of the archives of the state, and served also as a tribunal for the archon eponymus. Adjacent to the Metroum was the senate-house (*βουλευτήριον*), containing statues of Zeus the Counsellor, of Apollo, and of the Athenian demos; and close to the council-wall stood the Tholus, where the Prytanes usually held their feasts and sacrifices; while somewhat higher up were the statues of the eponymi, or heroes, who gave names to the Athenian tribes, with those of Amphiaraus, Lycurgus the orator, and Demosthenes. Near the latter stood a temple of Ares (Mars), having several statues within, and around it those of Hercules, Theseus, and Pindar, who was thus honoured for the praise he had bestowed upon the Athenians; close to which were the figures of Harmodius and Aristogeiton. All the statues here mentioned were carried away by Xerxes when he plundered Athens, but were afterwards restored by Antiochus, as we learn both from Pausanias and from Arrian. Above the Stoa Basileios was a temple of Hephæstus (Vulcan), and also one dedicated to Aphrodite (Venus) Urania, containing a statue of the goddess in Parian marble, executed by the chisel of Phidias; both of which edifices were situated near the western extremity of the hill or ridge of Areiopagus.[6]

Stoa Poecile. One of the most important of the Ceramic edifices was the Stoa Poecile, so called from the celebrated paintings with which it was adorned, although its more ancient name appears to have been Peisianactios. The paintings were almost exclusively devoted to the representation of national subjects, as the contest of Theseus with the Amazons, the battle of Marathon, and other achievements of the Athenians; and were mostly executed by Polygnotus, Micon, and Pamphilus, the most celebrated amongst the early Grecian artists. Here were also suspended the shields of the Scionæans of Thrace, together with those of the Lacedæmonians taken in the island of Sphacteria; and it was in this

Athens.

portico that Zeno first opened that celebrated school, which thence received the appellation of Stoic, and was destined to exercise a most powerful influence both on the philosophy and legislation of succeeding times. The Poecile is also memorable as the scene where no less than 1500 citizens of Athens are said to have been destroyed by the Thirty Tyrants. Some ancient walls which are still extant near the church of Panagia Fanaromeni, Colonel Leake supposes, with some probability, to be the remains of this once celebrated portico. Near the Stoa Poecile was a statue of Hermes Agoræus, which, from its position close to a small gate, was sometimes termed Ἑρμῆς πρὸς τῇ πολίδι.[1]

Ceramic Agora.

The epithet Agoræus naturally leads us to conclude that this brazen figure of the god, described by the Roman satirist as *furum aviumque maxima formido*, stood in the Agora or market-place, by much the largest portion of which was in the quarter of Ceramicus. Xenophon also informs us, that at certain festivals it was customary for the knights to make the circuit of the Agora on horseback, beginning at the statue of Hermes just mentioned, and paying homage as they passed along to the statues and temples around it.[2] There is sufficient reason to believe, however, that the Agora never extended to the southward and eastward of the ascent to the Acropolis; but it seems to have included a very large space to the west and north-west of the Propylæa; which is accounted for upon the supposition, which a number of circumstances conspire to render probable, that the market-place, or at least its most frequented parts, had shifted their position at different periods of the republic. In the more remote ages, when Acropolis or Cecropia was almost the only inhabited part of the site of Athens, it is natural to believe that the Agora resorted to from the neighbouring country must have been situated a little below the entrance of Cecropia, free admission to which could scarcely have been permitted to strangers in those barbarous ages. But when the principal sacred edifices were erected on the south side of the Acropolis, and the city began to spread over the valleys to the south and west of the citadel, the Agora may have extended into the western side of the same space, with that most ancient place of popular assembly, the Pnyx, above the middle of it. It has been supposed by Colonel Leake and others, that about the time of Augustus, when the city had been considerably extended in the north of the Acropolis, and when the Agora had been polluted by the massacre of the Athenians in the time of Sulla, a new Agora was built in the north of the Acropolis; and a portal still existing in that neighbourhood has been generally regarded as a remnant of this new Agora. But the style of this portal, as well as the inscriptions on it, show that it was not a gate, but a portion of a building erected out of the donations of Julius Cæsar and Augustus in honour of Athena Archegetis. As for the population of that part of the city, we know that in the time of Thucydides and Xenophon it was not occupied by houses, but consisted of gardens.[3] There is accordingly no ground for supposing that Athens ever had more than one Agora.[4]

Its sections or divisions.

Our detailed description of the Agora must necessarily be brief. It contained a street lined with Hermæ, and forming the communication between the Stoa Basileios and the Poecile. The Macra Stoa was a range of porticoes extending from the Peiraic gate to the Poecile, behind which rose the hill called Colonus Agoræus, where Meton erected a table for astronomical purposes. The Leocorium stood also in the Ceramicus, which, as classical readers know, is often used synonymously with Agora. Pausanias makes no mention of this monument, which was erected in honour of the daughters of Leos, who had devoted themselves for their country, and near which the tyrant Hipparchus was slain by Harmodius and Aristogeiton. The Ceramicus also contained the Agrippeium or theatre of Agrippa, the Palæstra of Taureas, and the Stoæ of the Thracians and of Attalus. The portion strictly appropriated as a market-place was divided into sections, distinguished from one another by appellatives descriptive of the various articles exhibited for sale. Thus we read of the γυναικεία ἀγορά, where women's apparel was usually sold; of the ἰχθυόπωλις ἀγορά, or fish-market; of the ἱματιόπωλις ἀγορά, or clothes-market; and of the ἀγορά Ἀργείων, Θεῶν, Κεράμων, where, among other things, stolen goods were, it seems, publicly disposed of. The quarter denominated Cyclus from its form, was the slave and provision-market. A peculiar stand was allotted to each vender, who, when he had once chosen his station, was not allowed afterwards to change it.[5] The common-hall of the Athenian mechanics was situated in the Ceramicus, which seems to have been the great resort of the lower orders, including courtesans, who, according to Lucian and the scholiast on Aristophanes, principally frequented this part of the city. In the north of the Acropolis, or the district commonly called that of the new Agora, there was an altar to Pity, and two gymnasia; one founded by Ptolemy the son of Juba the Libyan, the other supposed to have been established by Ptolemy Philadelphus, and each denominated Ptolemeium. To the northward of Fanaromeni there was found among the ruins,[6] many years ago, an inscribed pedestal, which had supported a statue of Ptolemy the son of Juba; and Juba is said by Pausanias to have been honoured with a statue in the Gymnasium of Ptolemy.[7] So much for the Ceramic edifices.

Theseum.

The next structure which demands our attention is the Theseium or temple of Theseus, which stood, and happily still stands, at no great distance from the site of the monuments last mentioned. The circumstances which led to the erection of this noble edifice are deserving of commemoration. About eight centuries after the death of Theseus, the Athenians suddenly became ashamed of the ingratitude of their ancestors towards their great benefactor, in driving him out of Athens to die by violence in a foreign country. This tardy fit of remorse is said to have been occasioned by a rumour, which readily gained belief, that the spectre of the patriot hero had been seen fighting against the Persian host at Marathon. The Pythia was consulted in reference to the supposed apparition, which of course was duly authenticated; and generously directed the Athenians to remove his remains to the city, which even his spirit had defended, and to honour him as a demigod. His bones, with a brazen helmet and a sword lying beside them, were discovered in the island of Scyrus, by Cimon, son of Miltiades. They were received at Athens with processions and sacrifices. Games and festivals were instituted in his honour; a heroum was erected to him on the Colonus Hippius, and a temple, the Theseium, in the city. This building was equalled in sanctity only by the Parthenon and Eleusinium; its sacred inclosure was so large as occasionally to serve as a place of military assembly. It was built about 465 years before the Christian era, and about 30 years anterior to the erection of the Parthenon.[8] The Theseium is a peripteral hexastyle, with 13 columns on the sides, and it faces the east.

Athens. The cella within measures 40 feet in length and 20 feet in breadth. It has a pronaos and a posticum, each of which is formed by a prolongation of the side walls of the cella, having two columns between the antæ; but the depth of the pronaos is greater than that of the posticum, and the depth of the portico of the pronaos is greater than that of the portico at the back of the temple. The side porticoes are only 6 feet in breadth; but the 34 columns of the peristyle are nearly 3 feet 4 inches in diameter at the base, and about 19 feet in height, with an intercolumniation of 5 feet 4 inches, except at the angles, where the interval is smaller. The stylobate is formed of only two steps; and the height of the temple, from the bottom of the stylobate to the summit of the pediment, is 33·5 feet. The eastern or chief front only of the temple was adorned with sculptures; and, accordingly, the ten metopes of that front, with the four adjoining metopes of either flank, are those in which the labours of Hercules and Theseus are represented in alto-relievo, while the other metopes are plain.[1] The roof of the cella of the Theseium is modern; the greater part of the beams and lacunaria of the porticoes are wanting; and the sculptures have been purposely defaced by the Turks. When the temple was converted into a Christian church, the two columns of the pronaos were removed to make room for the altar; and a door was at the same time pierced in the western wall. But when Athens was taken by the Turks, who were in the habit of riding into the churches on horseback, this door was shut up, and a smaller one made in the southern wall. In other respects, however, the temple is complete. It is formed entirely of Pentelic marble, and stands upon an artificial foundation constructed of large quadrangular blocks of ordinary limestone. At the north-western angle of the temple, where the hill upon which it stands is precipitous, six courses of the foundation now appear above ground, and are gradually receiving so much injury from the effect of the periodical rains as to threaten the safety of this part of the building. The sculptures of the Theseium are upon the 18 metopes already mentioned, upon a frieze over the entrance of the pronaos, and upon another over that of the posticum. All the metopes in the front of the temple which can be deciphered relate to the labours of Hercules, the kinsman, friend, and companion of Theseus; whilst those on the two flanks relate exclusively to the achievements of the hero to whom the edifice was more immediately dedicated. The subject of the frieze over the columns and antæ of the posticum or back vestibule was the most celebrated event in the life of Theseus, his contest with the Centaurs; and, from the analogy of the front and flank metopes, it may reasonably be presumed that the panel over the pronaos, which has been completely defaced, related to the exploits of Hercules. The interior of the Theseium, as we learn from Pausanias, was anciently decorated with paintings, representing the achievements of Theseus, particularly his battle with the Amazons, and the fight of the Centaurs and Lapithæ, where his prowess was most remarkably signalized.[2] The stucco upon which they were painted is still apparent, and shows that each painting covered the entire wall from the roof to within 2 feet 9 inches of the pavement. Athens.

Some difficulty exists as to the relative sites of the Anaceium and Aglaurium, which Pausanias next proceeds to describe. We know, however, that the Anaceium stood *below* the Aglaurium; and from comparing the statements of Herodotus, Pausanias, and Euripides in reference to the latter, Colonel Leake has made it pretty evident that the position of this ancient sanctuary of the Athenians was near the northern foot of the Acropolis, in some part of the precipices which are situated to the eastward of the Grotto of Apollo and Pan. These precipices were called the long rocks (μακραὶ πέτραι); and here it appears to have been that the Persians under Xerxes ascended the steepest part of the hill, near the temple of Aglauros, in order to scale the ramparts of the citadel; an enterprise in which they were completely successful. The Aglaurium was rather a sanctuary or sacred inclosure (ἱερὸν τέμενος) than a temple, and some traces of its existence are still discoverable near the centre of the north side of the Acropolis. The Anaceium,[3] or temple of the Dioscuri, a building of great antiquity, stood immediately below the Aglaurium, close to the rock of the Acropolis, and near the gate which now leads into an exterior inclosure of the citadel, forming the modern approach from the town to the Propylæa. It is said to have contained several paintings by Polygnotus and Micon. Near to the Aglaurium was the Prytaneium, where the written laws of Solon were deposited. It stood above the level of the main body of the city, and formed the commencement of a street called Tripodes, leading to the sacred inclosure of Bacchus, near the theatre; a circumstance which seems to fix its site at the north-eastern angle of the Acropolis, one of the very finest situations in Athens, commanding a view of the sea, as well as of all the northern part of the city and its plain. Not far from the supposed site of the Prytaneium is a church of Panagia Vlastiki, where are still seen the remains of some important building, probably the temple of Serapis, which is the first edifice mentioned by Pausanias upon descending from the Prytaneium into the lower parts of the city. "The ruins at the church of Vlastiki," says Colonel Leake, "are in a line between the new Agora and the arch of Hadrian: the building therefore to which they belonged probably stood in the street leading from the Agora to the Olympeium and Hadrianopolis, of which the arch of Hadrian formed the termination."[4] The numerous buildings erected by Hadrian in this part of the city were denominated Hadrianopolis, as we learn from an inscription on the remains of the triumphal arch just mentioned.[5] Aglaurium, &c.

The Olympeium, Olympieium, or Olympium, one of the most ancient temples in Athens, was supposed to have been originally founded by Deucalion. But it seems to have fallen into decay at a very early period; for about the year 530 before the Christian era, Peisistratus commenced a new and more magnificent structure upon the site of the old building. The ancient Athens, however, was not the only place Olympeium.

[2] For an account of the subjects of the sculpture in high relief which adorn the metopes of the front and two flanks of the temple, and the friezes over the posticum and pronaos, see Stuart's *Antiquities of Athens*, vol. iii., and especially Colonel Leake's additional note on the Theseium in his *Topography of Athens*, p. 392, to which we have been almost exclusively indebted for the above particulars.

[3] This building was named Ἀνάκειον because the Dioscuri (Castor and Pollux) were commonly called *οἱ ἄνακτες* by the Athenians. Plutarch, *Vit. Thes.*; Ælian, *Hist.* iv. 5; Harpocr.

[4] *Topography of Athens*, p. 134.

[5] Above the north-west side of the arch there is inscribed ΑΙΔΕΙΣΑΘΗΝΑΙΘΗΣΕΩΣ ΗΠΡΙΝΠΟΛΙΣ, that is, *αἵδε εἰσι Ἀθῆναι Θησέως ἡ πρὶν πόλις, This is Athens, formerly the city of Theseus*; and, on the opposite side, are the following characters: ΑΙΔΕΙΣΑΔΡΙΑΝΟΥΚΑΙΟΥΧΙΘΗΣΕΩΣΠΟΛΙΣ, *αἵδε εἰσι Ἀδριανοῦ καὶ οὐχὶ Θησέως πόλις, This is the city of Hadrian, not of Theseus.* Dr Chandler has supposed that the first words of the former inscription should be read *ἃ Τδεις Ἀθῆναι*, instead of *αἵδε εἰσι Ἀθῆναι*, or rather *αἵδ' εἰσ' Ἀθῆναι*; but Spon and Wheler, Stuart, and a multitude of others, including Kavasila (Cabasilas), a modern Greek, have all declared in favour of the former interpretation; and where the same contracted form of expression occurs in other inscriptions, Gruter, Crusius, and Meursius invariably resolve it as we have done. In both cases, however, the meaning is the same. That side of the arch which fronted the ancient city pointed it out, whilst the portion of the monument which looked towards the erections of Hadrian in like manner marked them out to the readers of the legend.

Athens.

in the world where it was found easier to begin than to finish a temple. The expensive wars in which the Athenians were not long afterwards engaged put a stop to the progress of the building; and nearly four centuries elapsed, including the most flourishing periods of the republic, before any attempt was made to complete it. At length, however, Antiochus Epiphanes, king of Syria, about the year 174 B.C., undertook this task, and a magnificent edifice of the Corinthian order was begun by Cossutius, a Roman architect. But upon the death of Antiochus in 164 B.C. the work was again interrupted; and on the capture of Athens by Sulla, 78 years afterwards, the columns prepared for the building were carried away by order of the conqueror, and erected as part of the temple of Jupiter Capitolinus at Rome. The Olympeium was in this imperfect and mutilated condition when the kings and states in alliance with or in subjection to Augustus undertook the completion of the edifice at their joint expense. But, from various causes, the work was once more interrupted; and the honour of completing and dedicating the temple, as well as of erecting the statue of the divinity, formed (if we may believe Pausanias) of ivory and gold, was reserved for Hadrian, six centuries and a half after its foundation by Peisistratus.[1] There can be little doubt that the cluster of magnificent columns of Pentelic marble at the south-east extremity of the city of Athens, near the Ilissus, belonged to the celebrated temple of the Olympian Zeus. They are of the Corinthian order, sixteen in number,[2] six feet and a half in diameter, and above sixty feet in height, standing upon an artificial platform, supported by a wall, the remains of which show that the entire peribolos or circuit must have been about 2300 feet, or little short of half a mile. From the existing remains, it appears that the temple consisted of a cella, surrounded by a peristyle, which had ten columns in front and twenty on the sides; that the peristyle, being double on the sides and quadruple at the posticum and pronaos, consisted altogether of 120 columns; and that the whole length of the building was 354 feet, and its breadth 71. "Such vast dimensions," says Colonel Leake, "would alone be sufficient to prove these columns to have belonged to that temple, which was the largest ever built in honour of the supreme pagan deity, and one of the four most magnificent ever erected by the ancients, even if Thucydides had not pointed out this side of the city as the position of the Olympeium, or if Vitruvius had not left us a description of this edifice exactly conformable with the existing ruins."[3]

Temples of Hera and Zeus Panhellenius, &c.

To the taste and munificence of Hadrian Athens was also indebted for a temple of Hera (Juno), another dedicated to Zeus (Jupiter) Panhellenius, and a temple common to all the gods, or Pantheon. But the most remarkable edifice next to the Olympeium, erected by this emperor, was that which has been denominated the Stoa or Gymnasium of Hadrian. When complete, it was a quadrangle of 376 feet by 252, adorned at the western end with a portal and colonnade of Corinthian columns, 120 in number, and each three feet in diameter; but of these, which were formed of Phrygian marble, only ten are at present standing. In the centre are the ruins of a building which now forms part of the church of Megali Panagia, and consist, on one side of the remains of an arch, and on the other of an architrave, supported by a pilaster, and three Doric columns, each one foot nine inches in diameter, and of a declining period of the arts: round the inside of the inclosure, at a distance of twenty-three feet from the wall, are also vestiges of a colonnade; and in the northern wall, which still exists, there is one large quadrangular niche thirty-four feet in length, and two circular niches equal to it in diameter. The general form and distribution of this building, which Pausanias notices as the most magnificent of Hadrian's works, are those of a stoa, or place of resort for walking, conversation, and reading; and the apartments projecting from the wall of the peribolos accord precisely with the *οἰκήματα* mentioned by Pausanias, which were resplendent with alabaster and gilding, and adorned with pictures and statues. The building at the church of the great Panagia in the centre answers, Colonel Leake thinks, to the library with which we know from several ancient authors[4] besides Pausanias, that this magnificent stoa was provided.[5]

Athens.

Tripodes, Lenæum, Dionysiac Theatre, &c.

Besides the street leading from the Prytaneium to the Olympeium, there was another which branched off from the same place towards the Lenæum or sacred inclosure of Bacchus, adjacent to the theatre, which was called the Tripodes, from the tripods there dedicated by the leaders of the chori victorious in the scenic contests decided in the Dionysiac theatre. Several of these tripods were placed upon temples dedicated to Bacchus and other deities, and erected either in the quarter of the Tripodes or within the inclosure of the Lenæum; others, again, stood upon columns and rocks near the theatre, as the remains of the monuments still indicate. Of the former description was the beautiful little choragic monument of Lysicrates, vulgarly called the Lantern of Demosthenes, the apex of which proves beyond a doubt that it once supported a tripod, while its closed construction shows that the victorious choragus who built this gem of art (*νεὼς ὑποκείμενος τῷ τρίποδι*) preferred bestowing all the expense on external decorations.[6] From the inscription on this monument it appears to have been erected in the archonship of Evænetus, in the year 335 B.C.;[7] and it is consequently the oldest known specimen of the Corinthian order, although considerably posterior to the epoch of its invention.[8] Colonel Leake thinks that the street of Tripodes passed at the foot of the rocks under the east end of the Acropolis; and that, after reaching the south-eastern angle of the rocks, it had one branch leading into the Lenæum, and another into the theatre of Bacchus. The Lenæum, situated on the western side of the theatre, was a most ancient sanctuary of Bacchus; having within its peribolos or inclosure two other temples similarly dedicated, with a couple of statues, one of which was surnamed Eleuthereus,—and containing several pictures representing different events in which the rosy god

[5] *Topography of Athens*, 120. Spon and Wheler conceived this building to be the temple of Jupiter Olympius, in which they were certainly mistaken; and Stuart thought it the Poecile, which is incompatible with the fact he himself admits, that the columns were the work of Roman times.

[6] Stuart's *Antiq. of Athens*, vol. i. c. 4; Leake's *Topography*, 155.

[7] The inscription, which is upon the architrave, testifies that Lysicrates, son of Lysitheides, led the chorus when the boys of Acamantis gained the victory, when Theon played the flute, when Lysiades wrote the piece, and when Evænetus was archon.

[8] This order was first employed in the construction of the temple of Athena Alea at Tegea about the year 385 B.C., or half a century prior to the period in question. (Pausan. *Arcad.* c. 45.)

Athens. was believed to have participated. This is the temple to which Thucydides alludes as that of Dionysus in Limnis, or Bacchus in the marshes.[1] The Dionysiac Theatre was situated near the south-eastern angle of the Acropolis, where vestiges of it are still to be seen. Like most of the other theatres of Greece, its extremities were supported by piers of solid masonry, while the middle of it was excavated in the side of the hill. From the existing ruins, however, it is difficult to form any correct estimate of the dimensions of this theatre; but if we are to credit Plato's statement, that it was capable of containing more than 30,000 spectators,[2] it must have descended much lower down into the plain than has been generally imagined, or than the actual remains would lead us to suppose. The Hierum of Epidaurus, which could not have contained more than 15,000 spectators, allowing only eighteen inches for each person, was 366 feet in diameter; and the theatres at Argos and Sparta, as well as that near Dramatzus in Epirus, were about 500 feet in diameter, yet could not have admitted more than 30,000 spectators, allowing for each the width of seat or room just mentioned. If Plato's statement be correct, it seems therefore to follow, that the diameter of the Dionysiac theatre must have been not less than from 450 to 500 feet, and consequently that it must have extended quite close to the foot of the hill, where, indeed, the level space necessary for the orchestra and the scene could alone have been found.[3] This celebrated theatre contained statues of all the great tragic and comic poets, the most conspicuous of which were naturally those of Æschylus, Sophocles, and Euripides, among the former, and that of Menander among the latter; and Dicæarchus informs us that it was accounted the most beautiful structure of the kind in existence. A little to the east ward stood the Odeium of Pericles, with a roof formed out of the masts and yards of the Persian ships captured at Salamis, and rising to a point like the pavilion of Xerxes, which the whole structure indeed was intended to represent. It was richly decorated with columns; and during the dominion of the Thirty Tyrants, was generally occupied by their satellites. During the siege of Athens by Sulla, Aristion, general of Mithridates, who was intrusted with the defence of the city, set fire to this monument of Athenian glory, lest the enemy should make use of the timber for the purpose of assaulting the Acropolis; and although Vitruvius informs us that it was afterwards restored at the expense of Ariobarzanes, king of Cappadocia, not a vestige or trace of the edifice remains. In the immediate vicinity of the citadel were a temple of Æsculapius, with a fountain; the temples of Themis, Aphrodite Pandemos, and Persuasion; the monument of Hippolytus; besides the temple of Demeter Chloe, some remains of which are supposed to exist at the foot of the Acropolis, near the ascent which formerly led to the citadel.[4]

Acropolis. The ancient city of Cecrops is now a fortress or citadel, with a thick irregular wall inclosing a large area about twice as long as it is broad, and standing on the outer ledges of an elevated rock abruptly terminating in precipices on every side, except the front, which is towards the Peiræus or west, and by which alone it is accessible. Some portions of the ancient wall may still be seen on the outside, particularly at the two extreme angles; and in many places it is patched with fragments of columns and marbles taken from the ruins. Athens. The physical character of this remarkable rock continues nearly the same as in the days of the most remote antiquity; and notwithstanding all the devastations which war, time, and fanatical barbarism have committed, it still contains a large portion of the remaining antiquities of Athens, and consequently demands a corresponding share of the researches both of the artist and topographer. Anciently the Acropolis was filled with monuments of Athenian glory, and exhibited an amazing concentration of all that was most perfect in art and most magnificent in architectural decoration. It appeared, so to speak, as one entire offering to the divinity, surpassing in excellence, and unrivalled in richness and splendour. It was the peerless gem of Greece, the glory and the pride of art, the wonder and envy of the world. Heliodorus, surnamed Periegetes or the Guide, employed no less than fifteen books in describing it; the curiosities of various kinds, with the pictures, statues, and pieces of sculpture, supplied Polemo Periegetes with matter for four volumes; and Strabo seems to think that as many more would have been required for a minute description. The number of statues, in particular, was prodigious. Tiberius Nero, who had a remarkable taste for appropriating works of art which the genius and means of others had executed, plundered the Acropolis, as well as Delphi and Olympia; yet notwithstanding this spoliation, Athens, in the time of Pliny, had no fewer than three thousand remaining, of which the most valuable portion was in the Cecropian city on the rock. Even Pausanias seems to be distressed by the multiplicity of objects which here engaged his attention, and uncertain where to commence his description. Such *was* the Acropolis. What it *is*, Stuart and Revett, and Cockerell and Leake, and other writers, have told us; and to their learned and accurate researches we are indebted for the correct knowledge, which we have at length attained, of those magnificent buildings which adorned the citadel of Athens. We do not say that many curious discoveries connected with the monuments of the Acropolis may not still be made, when its platform shall have been cleared of the wretched buildings which now cover its surface and disfigure its appearance; but in regard to the three great edifices, namely, the Propylæa, the Parthenon, and the Erechtheium, it is probable, from what has been already discovered, that but little remains to be done.

Propylæa. The western side of the Acropolis, which, as we have already said, furnished, and still furnishes, the only access to the summit of the hill, was about 168 feet in breadth; an opening so narrow that, to the artists of Pericles, it appeared practicable to fill up the space with a single building, which, in serving the main purpose of a gateway, should contribute to adorn as well as to fortify the citadel. This work, the greatest production of civil architecture in Athens,[5] which rivalled the Parthenon in felicity of execution, and surpassed it in boldness and originality of design, was begun in the archonship of Euthymenes, in the year 437 B.C., and completed in five years, under the directions of the architect Mnesicles, at the enormous cost, if we may believe Heliodorus, of two thousand and twelve talents.[6] Of the space which formed the natural entrance to the Acropolis, 58 feet near the centre were left for the great artificial entrance, and the

[4] *Ibid.* 162.

[5] Philostratus, in his *Life of Apollonius Tyanæus*, says, Περικλεῖ μὲν Προπύλαια πρὸς φιλοτιμίαν ἤρκει καὶ Παρθενών, l. ii. c. 5; and Demosthenes, in his oration against Androtion, gives a similar indication of the Propylæa having been considered upon a level with the Parthenon in point of architectural skill and decoration: οἱ τὰ Προπύλαια καὶ τὸν Παρθενῶνα οἰκοδομήσαντες ἐκεῖνοι καὶ τἄλλα πάντα ἀπὸ τῶν βαρβάρων ἱερὰ κομήσαντες, κ. τ. λ. p. 597, ed. Reiske.

[6] This is incredible for many reasons. In particular, it appears, from Thucydides, that the expense of *all* the works of Pericles, including the Odeium, the mystic temple at Eleusis, the Parthenon, and one of the long walls, as well as the Propylæa, did not amount to three thousand talents; and it is therefore inconceivable that the last-mentioned edifice, one of five of which the Parthenon was the chief, should have cost two-thirds of this sum. See a very learned note on this subject by Colonel Leake. (*Topography of Athens*, p. 406.)

Athens. remainder on either side was closed by wings projecting 32 feet in front of the grand central colonnade. The entire building received the name of Propylæa from its forming the vestibule to the five gates or doors, still in existence, by which the citadel was entered.[1] The wall in which these doors were pierced was thrown back about 50 feet from the front of the artificial opening of the hill; and the whole may, therefore, be said to have resembled a modern fortification, the Propylæum properly so called representing the curtain, and each of the two wings presenting a face and flank or gorge like two adjoining bastions. This incomparable edifice was constructed entirely of Pentelic marble. The Propylæum or great vestibule in the centre consisted of a front of six fluted Doric columns, mounted upon four steps which supported a pediment, and measuring five feet in diameter and near 29 in height, with an intercolumniation of 7 feet, except between the two central columns, which were 13 feet apart in order to furnish space for a carriage-way. Behind the Doric colonnade was a vestibule 43 feet in depth, the roof of which was sustained by six Ionic columns in a double row, so as to divide the vestibule into three aisles or compartments; and these columns, although only three feet and a half in diameter at the base, were, including the capitals, nearly 34 feet in height, their architraves being on the same level with the frieze of the Doric colonnade. The ceiling was laid upon marble beams, resting upon the lateral walls and the architraves of the two rows of Ionic columns; those covering the side aisles being 22 feet in length, and those covering the central aisle 17 feet, with a proportional breadth and thickness. Enormous masses like these, raised to the roof of a building, standing upon a steep hill, and covered with a ceiling which all the resources of art had been exhausted to beautify, might well excite the admiration of even a plain matter-of-fact topographer like Pausanias, and at once account for and justify the enthusiasm with which he expresses himself when speaking of the roof of the Propylæa.[2] Of the five doors at the extremity of the vestibule, the width of the central and largest was equal to the space between the two central columns of the Doric portico in front, which was the same as that between the two rows of Ionic columns in the vestibule; but the doors on either side of the principal one were of diminished height and breadth, and the two beyond these again were still smaller in both dimensions. These five gates or doors led from the vestibule into a back portico 18 feet in depth, which was fronted with a Doric colonnade and pediment of the same dimensions as those of the western or outer portico, but placed upon a higher level, there being five steps of ascent from the level of the latter to that of the former. From the eastern or inner portico there was a descent of one step into the adjacent part of the platform of the Acropolis.

Wings. The wings of the Propylæa were nearly symmetrical in front, each presenting on this side a wall adorned only with a frieze of triglyphs, and with antæ at the extremities. The extreme simplicity of the wings in this direction was characteristic of the work of defence of which they formed so important a part; while the flanks of the bastions (if we may be allowed the expression) were also uniform in their construction, each presenting a Doric front of three columns in antis, each three feet in diameter, supporting pediments, the summits of which were on a level with the frieze of the Propylæum properly so called. Besides, the inner or southernmost column of each wing stood in a line with the great Doric columns of the Propylæum; and as both these columns and those of the wings were upon the same level, the three porticoes were all connected together, and the four steps which ascended to the Propylæum were continued also along the porticoes of the two wings. But here the symmetry of the building ended; for, in regard to interior size and distribution of parts, the wings were exceedingly dissimilar. In the northern or left wing, a porch of twelve feet in depth conducted by three doors into a chamber of 34 feet by 26, the porch and chamber thus occupying the entire space behind the western wall of that wing; whereas the southern or right wing consisted only of a porch or gallery of 26 feet by 16, which, on the south and east sides, was formed by a wall connected with and of the same thickness as the lateral wall of the Propylæum, and, on the west side, had its roof supported by a narrow pilaster, standing between the north-west column of the wing and an anta, which terminated its southern wall. In front of the southern or right wing there stood, so late as the year 1676, a small Ionic temple, dedicated to Niké Apteros (Wingless Victory). Wheler informs us that it was built of white marble, and about fifteen feet in length by eight or nine in breadth; and we learn from Spon that it was then used by the Turks as a powder-magazine.[3] The left wing of the Propylæa was decorated with paintings by Polygnotus, representing a series of events connected with the siege of Troy; and the structure was ornamented with equestrian statues. After the ruin of Athens, the Propylæa ceased to be the entrance of the Acropolis. The passage between the columns of the centre was walled up almost to their capitals, and above was a battery of cannon. The way wound before the front of the ancient structure; and turning to the left among rubbish and wretched walls irregularly huddled together, the stranger proceeded to the back of the vestibule and the five door-ways, without almost suspecting that he was in the midst of that celebrated structure which formed the external glory and defence of the rock of Cecrops.[4]

Athens.

Parthenon. The Parthenon, or temple of the Virgin Goddess, was placed upon the highest platform of the Acropolis, which was so far elevated above its western entrance that the pavement of the peristyle of this renowned edifice was upon the same level as the capitals of the columns of the eastern portico of the Propylæa. It was also called Hecatompedon (from its being a hundred feet broad), and was constructed entirely of white marble from the quarries of Mount Pentelicus. It consisted of a cella, surrounded with a peristyle, having eight Doric columns in the two fronts, and seventeen in the sides, or forty-six in all; each column six feet six inches in diameter at the base, and thirty-four feet in height, standing upon a pavement or platform, to which there was an ascent of three steps. The total height of the temple above its platform was about 68 feet, its length 228, and its breadth 102 feet English. Within the peristyle, at both ends, there was an interior range of six columns, five feet and a half in diameter, standing before the end of the cella, and forming a vestibule to its door, two steps above the pavement of the peristyle. The cella, which was 63 feet in breadth within, was divided into two unequal chambers, of which the western was about 43½ feet in length, and the eastern 98 feet. The ceiling of the former was supported by four columns of about four feet in diameter, and that of the latter by sixteen columns of about three feet.

[1] Heliod. *apud Harpocrat.* v. Προπύλαια.

[2] Τὰ δὲ Προπύλαια λίθου λευκοῦ τὴν ὀροφὴν ἔχει, καὶ κόσμῳ καὶ μεγέθει τῶν λίθων μεχρί γε ἐμοῦ πρεσβύς. (*Attic.* c. 22.)

[3] This little gem of ancient architecture has lately been almost completely restored; for during the excavations made in 1835, nearly all the stones of which it had originally consisted were recovered, and under the superintendence of very competent persons it has been rebuilt with the original materials and on its original site, where it has the appearance of an entirely new building.

[4] In the year 1853 M. Beulé, at the expense of the French government, removed the rubbish of the two Turkish batteries that covered up the true entrance to the Athenian Acropolis, and discovered below the unseemly mass the two towers that formed the defences of the gate, and between them a marble curtain, with remains of a Doric entablature over a Doric doorway of a simple but beautiful style. Within this the fine marble stairs that formed the ascent to the Propylæa are still entire.

Athens.

Since the time of Stuart and Leake, the Greek government has removed the whole of the ruins that encumbered the existing remains, and the Turkish tower and mosque, and the ground plan of the Parthenon has been more accurately ascertained. The accurate measurements were made by Mr Pennethorne in 1837, confirmed in 1838 by two German artists, M. Hofer and M. Schubart, and the plans laid down by Geo. Knowles in 1850. The singular discoveries that have been thus brought to light are not unimportant to architecture. It is discovered that the lines formerly supposed to be straight lines, are regularly formed segmental curves of a long radius. Thus the lines of the pediment and of the surface of the pavement are found to be parabolic segments of large radius.[1] The platform is found to be just 233 feet by 108 feet. The exterior dimensions of the cella = 158 feet 6 inches by 72 feet 6 inches. The cella was divided by a wall of 4 feet in thickness into the Parthenon proper, the interior of which is 97 feet 6 inches by 64 feet, and an opisthodomos of 44 feet 6 inches, by 64 feet. Thickness of the end walls of the cella, 7·75 feet; of the side walls, 4 feet. The diameter of the base of the columns is 6 feet 6 inches. The intercolumniations are 8 feet, except at the angles of the peristyle on the sides, where these are only one diameter of the columns. The principal division of the cella had two interior rows of columns of ten in each row, with three additional at the west end. They were 11 feet from the side walls of the cella and the septum. The space between the rows is 23 feet. The statue of the goddess is now ascertained to have stood within the columns, 70 feet from the porch of the eastern portico, and 34 feet from the septum dividing the Parthenon from the opisthodomos. The opisthodomos had 4 interior Doric columns of the same diameter as the columns of the peristyle, placed 17 feet from the side walls of the cella, and 11 feet from the septum. In the eastern chamber of the Parthenon, the smallness of the diameter of the columns leaves little doubt that there was an upper range, as in the temples of Pæstum and Ægina. But it is to be lamented that no remains of any of them have been found, as these might have presented new proofs of the taste and invention of the architects of the age of Pericles. Such, then, was the simple construction of this magnificent temple, which, by its united excellencies of materials,[2] design, and decoration, internal as well as external, has been universally considered the most perfect which human genius and skill ever planned and executed. Its dimensions were sufficiently large to produce an impression of grandeur and sublimity, which was not disturbed by any obtrusive subdivision of parts; and, whether viewed at a small or a great distance, there was nothing to divert the mind of the spectator from contemplating the unity as well as majesty of mass and outline; circumstances which form the first and most remarkable characteristic of every Greek temple erected during the purer ages of Grecian taste and genius. Nor was it until the eye had become satiated with the contemplation of the entire edifice that the spectator could be tempted to examine the decorations with which this building was so profusely adorned; for the statues of the pediments, the only decoration which was very conspicuous from its magnitude and position, being inclosed within frames, which formed an essential part of the design of either front, had no more obtrusive effect than an ornamented capital to a single column.[3]

Athens.

Decorations.

It is not our intention, in this place, to attempt any detailed or minute description of an edifice which would require a volume for its complete illustration. We may observe, generally, that as it was one of the great objects of Pericles to furnish employment in every branch of art to the ingenious and skilful artists with whom Athens at that period abounded, so he had contrived that the temple should be of a design the best adapted to the decorations of sculpture, and that it should be adorned with every species of it which was most esteemed among the Greeks. Within the cella was a specimen of chryselephantine sculpture, having but one rival in Greece, and that by the same master; under the colonnade, and in other parts of the temple, stood numerous statues in bronze; in the reti or pediments were two compositions near eighty feet in length, each consisting of about twenty entire statues of colossal size; under the exterior cornice, in harmony with the projecting features of that part of the building, were ninety-two groups, raised in high relief, from tablets about four feet three inches square; and, lastly, along the outside of the cell and vestibules ran a frieze of about three feet four inches in breadth and 520 in length, to which a relief, slightly raised above the surface of the naked wall

---

[1] This has been found to hold particularly in the Parthenon, Theseium, and also in the Corinthian temple of Jupiter Olympius, but especially in all the Doric remains.

The curves are so gentle as to be not perceptible to one standing directly in front, unless the eye be practised in such observations; but if the spectator be placed at one end, and look along the course, it will be seen.

This explains an obscure passage in Vitruvius, in which the words *scamilli impares* had formerly puzzled the commentators, but which has been correctly translated by Wilkins.

The following table is given by Mr Penrose in his *Investigation of the Principles of Athenian Architecture*:—

	Feet in Length.	Actual Rise.	Rise in 100 Feet.
1. Temple of Jupiter Olympius.			
Flank	354·2	·25 nearly.	·07
2. Surbase of Parthenon, or first temple,			
Front	104·2	·150	·145
Flank	221·	·233	·105
3. Stylobate of Parthenon.			
Front	101·3	·228 = flank × $\frac{1}{1000}$	·225 = $\frac{8}{9}$ ·145 } very
Flank	228·1	·355	·156 = $\frac{8}{9}$ ·105 } nearly.
Entablature in front	100·2	·171 = $\frac{3}{4}$ ·228	·171
Ditto on flanks restored	227·	·307	·135
4. Theseum.			
Front	45·	·063	·140
Flank	104·2	·101	·100
5. Propylæa.			
Entablature from E. portico	68·1	·119	·175

It thus appears, that in the Theseium and the first Parthenon the agreement is remarkable; but it will be seen that the curvature of the lines in the Parthenon of Pericles is greater by one-half. "The effect of the curvature in the temple of Theseus may have shown the architect that an increase of curvature would be attended with advantage." This introduction of gently curved lines no doubt adds to that peculiarly harmonious blending of the parts of the architecture so observable in all genuine Grecian buildings.

[2] The beautiful white marble with which nature furnished the Athenians was undoubtedly one of the great concurring causes of their unrivalled pre-eminence in architecture and statuary. Admitting as fine a surface, and presenting as beautiful a colour, as ivory, with a still sharper edge, it was admirably calculated to encourage the successive efforts of artists studious to excel their predecessors in the effects produced. (*Topography of Athens*, 211, 212.)

[3] *Topography of Athens*, p. 209, *et seq.*; Stuart's *Antiq. of Athens*, vol. ii. p. 57.

Athens. which it crowned, was peculiarly applicable. This frieze represented the procession to the Parthenon on the grand quinquennial festival of the Panathenæa. No part of the work is now attached to the temple, but a tolerably correct idea of it may be formed from the drawings of Carrey, taken before the explosion which ruined the building, added to the designs of Stuart, and the fragments of the original which have been disinterred from the ruins and are now deposited in the British Museum. The procession is represented as advancing in two parallel columns from west to east; one proceeding along the northern, and the other along the southern side of the temple, part facing inwards after turning the angle of the eastern front, and part meeting towards the centre of that front. Of the metopes on the frieze of the peristyle, ninety-two in all, viz., fourteen on either front and thirty-two on either flank of the temple, the greater part on the northern side and the two fronts have perished by wanton violence or by casual destruction; whilst of those which belonged to the southern side, where the progress of dilapidation had been less ruinous, fifteen are now in the British Museum and one in Paris. From these fragments, together with the drawings of Carrey and Stuart, it has been conjectured, with much probability, that the metopes of the northern side related to the war of the Amazons, whilst those on the opposite side of the temple related principally to the other great fabulous Athenian contest with the Centaurs. The two pediments of the temple were decorated with magnificent compositions of statuary, one representing the birth of Athena (Minerva), and the other the contest between that goddess and Poseidon (Neptune) for the possession of Attica; the birth being delineated on the western and the contest on the eastern pediment. The statue of the virgin goddess stood in the eastern chamber of the cella, and consisted of ivory and gold. On the summit or apex of the helmet was placed a sphinx, with griffins on either side. The figure of the goddess was represented in an erect martial attitude, and clothed in a robe reaching to the feet. On the breast was a head of Medusa wrought in ivory, and a figure of Victory about four cubits in height. The goddess held a spear in her hand, and an ægis lay at her feet; while on her right, and near the spear, was a figure of a serpent, believed to represent that of Erichthonius. According to Pliny, the entire height of the figure was twenty-six cubits; and the artist Phidias had ingeniously contrived that the gold with which the statue was encrusted might be removed at pleasure. The battle of the Centaurs and Lapithæ was carved on the sandals; the gigantomachia and the battle of the Amazons were represented on the ægis which lay at her feet; and on the pedestal was sculptured the birth of Pandora. Pausanias also notices statues of Iphicrates, Pericles, his father Xantippus, Anacreon, and a brazen Apollo by Phidias. A portion of the southern wall was adorned with the battle of the giants; and here also were represented the conflict of the Athenians and Amazons, the battle of Marathon, and, lastly, the defeat of the Gauls in Mysia, sculptured at the expense of Attalus. The statue of Zeus Polieus stood between the Propylæa and the Parthenon; and the brazen colossus of Athena by Phidias, dedicated from the tenth of the spoils of Marathon, and commonly called Athena Promachos, appears to have occupied some part of the space between the Erechtheium and Propylæa, near the Pelasgic or northern wall. The architect of the Parthenon was Ictinus, who appears to have designed as well as executed the building; while Phidias had the control of the whole sculptural decorations, and with his own unrivalled hand executed those prodigies of art with which this great temple was adorned.[1]

Erechtheium, &c. The Erechtheium, or Temple of Erechtheus, so called from its reputed founder Erechtheus, otherwise named Erichthonius, stood on the northern side of the Acropolis, and was one of the most ancient structures of Athens, being alluded to by Homer in the second book of his *Iliad*. There is, however, some confusion respecting this edifice, which seems to have been of a double construction, or divided into two parts, from the circumstance of the entire building being often called the temple of Athena Polias as well as the Erechtheium; a practice which, as Colonel Leake remarks, is not at all surprising, considering that the temple of Athena Polias was the most important part of the building, and that the statue of the goddess here worshipped was the most sacred in Attica, not even excepting that of the Parthenon. The truth, however, seems to be, that the Erechtheium contained two subdivisions; the eastern or more important forming the temple of Athena Polias, the peculiar protectress of the citadel; and the western, that of Pandrosos. The former had a hexastyle front; before the colonnade was an altar of Zeus, and under it were altars of Poseidon and Hephæstus; on the wall of the portico were the pictures of the Butadæ; and within the cella were the Erechtheian salt-well, the wooden statue of Athena, with the lamp and brazen palm-tree before it, the altar of oblivion, the sacred serpent, the wooden statue of Hermes, the chair of Dædalus, and the Persian spoils. The Pandrosium, or chapel sacred to Pandrosos, one of the daughters of Cecrops, consisted of two chambers, of which the western was narrow, and opened into the portico at either end. The northern portico consisted of six Ionic columns, four in the front, with one on either flank; and it stood not far from the edge of the precipice, at the foot of which was the *temenos* of Aglauros. The southern portico was smaller than the northern, and its roof was supported by six caryatides, standing upon a podium, and disposed like the columns of the northern portico, four in front and two on the flanks. In the western or narrow chamber of this chapel grew the tree of Athena, and the crooked Pancyphus, which was held in such high veneration by the Athenians, and which the Persians, during their invasion, had burned but not destroyed. As to the eastern or interior chamber, which was contiguous to the cella of Athena Polias, Colonel Leake thinks with Stuart that it formed the Cecropium, and quotes an inscription which countenances that opinion. "That Cecrops," says he, "was buried in this edifice appears to have been the common belief; and upon an inscribed marble (brought to England by Dr Chandler, and presented by the Society of Dilettanti to the British Museum), wherein different parts of this building are specified, we find the Cecropium mentioned in a manner which leaves no doubt of its having been an integral part of the building." The number of statues in the Acropolis was prodigious; and there were likewise several hiera or sanctuaries, such as that of Zeus Polieus, Artemis (Diana) Brauronia, and the genius of good men. The whole of the Acropolis was surrounded by walls built on the natural rock of which the entire hill is composed. But the most ancient part of these defences was constructed by the Tyrrhenian Pelasgi, who, in the course of their multifarious migrations, settled in Attica, and were employed by the Athenians of that early period in the erection of those ramparts which are often mentioned in the history of Athens under the name of Pelasgicum. Before the Persian war, however, they had fallen into decay; for on that occasion it was found necessary to erect palisades and other temporary defences. At a subsequent period the hill was re-fortified by Cimon and Themistocles; and it is probable that the greater part of the existing wall, although disfigured by the reparations of various ages, consists of the original Hellenic work hastily raised by these celebrated men, before the alarm occasioned by the Persian invasion had entirely subsided. "A part of the southern wall," says Colonel Leake, "where the profile is not less than 60 feet in height,

[1] *Topography of Athens, ubi supra;* Pliny, l. xxxvi. c. 5; Pausan. *Attic.* 25.

appears in particular to consist almost entirely of the ancient Cimonian work; and the centre of the northern side still bears the strongest evidence of the haste with which Thucydides describes the fortifications of Athens to have been restored after the Persian war, when the Athenians returned to the city upon the departure of the barbarians, and found nothing left but a small part of the walls, and some of the houses which had been occupied by the Persian grandees."[1]

Grotto of Pan, Areiopagus.

In his descent from the Propylæa, in the direction of the outer Ceramicus and Academy, Pausanias describes the Cave or Grotto of Pan and the Areiopagus, both of which lay nearly in his route, and were the only objects of importance which had not yet been noticed by him. The grotto sacred to Apollo and Pan he describes as a cavern converted into a temple, and as situated under the Propylæa, near to a spring of water. Now, under the wall of the northern wing of the Propylæa, near the road which forms the present access to the citadel from the centre of the town are both the cavern and the spring; the former containing two excavated ledges for the altars and statues of the two deities, together with several niches for votive offerings; and the latter supplying water to an artificial fountain a little way down the hill, whence the streamlet is conveyed by means of an aqueduct to the principal mosque, near the Bazaar.[2] The Areiopagus, or hill of Ares, so called, it is said, in consequence of that god having been the first person tried there for the crime of murder, was beyond all doubt the rocky height which is separated from the western end of the Acropolis by a hollow forming a communication between the northern and southern divisions of the city. It appears, however, that the court of Areiopagus, and the temple of the Semnæ occupied only the eastern or highest summit of the hill, which agrees with the authorities indicating that other buildings were situated on the more western parts of the ridge. This court consisted originally of an open space, in which were an altar dedicated to Athena Areia, and two rude seats of stone for the plaintiff and defendant, or the accuser and accused, as the case might be. But we learn from Vitruvius, that at a later period this space was inclosed and roofed in with tiles, and the ancient mode of administering justice in the open air altogether abandoned. The Persians occupied a position on the Areiopagus at the time when they made their attack on the western end of the Acropolis. Near to the spot on which the court stood was the temple of the Furies, as well as the building on which the sacred ship of the great Panathenaic festival was deposited.[3]

Pnyx, Museium, &c.

In ancient times, a place at the foot of the Pnyx was the most common place of public assembly, especially during elections; but latterly it was less frequented for that purpose than the Dionysiac theatre, which has been already described. It appears to have been situated over against the Areiopagus, in view of the Propylæa, and not very far from the city walls; and it was constructed for the meetings of the people, not with the magnificence of a regular theatre, but with a simplicity characteristic of the earlier and severer age of Grecian liberty. The orators addressed the people, not from rostra splendidly decorated, but from a Βῆμα, or plain pulpit of stone, which looked to the sea. Some traces of this ancient structure still exist on a height or eminence, the situation and bearings of which, to the N. of the Museium, and the W. of the Areiopagus, accord perfectly with the position of the Pnyx, as determined by the statements of the Greek writers.[4] The whole range of hills which rises to the S.W. of the citadel, and above the ancient place of the popular assembly, bore the name of Pnyx. Plato informs us that it was opposite the Pnyx, and Antigonus Carystius relates a fabulous story, which would lead us to imagine that anciently it approximated more closely to the Acropolis than is at present the case. The Museium was another elevation S. of the Pnyx, and, like the Pnyx, it was within the peribolus or circumference of the ancient walls. It derived its name from the poet Musæus, who was believed to be interred there. At a later period a monument was erected on this eminence by Philopappus, a descendant of the kings of Commagene in Syria, who, having been consul in the reign of Trajan, retired to Athens (as we learn from the inscription) to spend the remainder of his days "from toils and cares remote," in the bosom of that renowned city. Among the inferior courts of judicature mentioned by Pausanias, after describing the Areiopagus, were the Parabystum, where petty causes were tried; the Trigonum, so called from its shape; and the Batrachium and Phœnicium, which probably received their names from some peculiarities of colour in the edifices where they were held. The Palladium was a court where persons accused of murder were commonly tried. Those, however, who confessed to the act of slaying, but set up a justification of the deed—as, for example, that it had been done in self-defence—were sent to be judged in the Delphinium, a tribunal which probably derived its name from being situated near the temple of Apollo Delphinius.[5]

This completes our survey of the principal buildings, monuments, and localities, within the city, which we have described as fully as the limits to which the present article is confined would possibly admit; omitting nothing which we considered of material importance, either for conveying a just notion of the ancient splendour and magnificence of Athens, as contrasted with its actual state of decay and ruin, or for enabling the reader to understand and appreciate the innumerable allusions, references, and descriptions, with which the Greek writers, whether poets, historians, philosophers, or orators, abound.

Cœle, Melite, Colyttus.

The whole of the north-western part of the city, comprising the hills Museium, the Pnyx, and the hill of the Nymphs, appears to have borne the name of Melite; but it was subdivided into quarters. The valley between the Museium and Pnyx was called Colyttus or Collytus,[6] and the district north of the Pnyx and south of the hill of the Nymphs bore the name of Scambonidæ. The whole of this part of the city appears to have been densely peopled, and many of the illustrious persons in Athenian history are said to have dwelt there.[7] On the south of the Museium the city extended a little way beyond the river Ilissus, and the south-western part of the city bore the name of Cœle, that is, hollow or low ground; it appears to have been mainly used as a burying-ground.

[2] The position of the cave of Apollo and Pan is exactly represented on a coin of Athens, which has been published by Stuart (*Antiquities of Athens*, vol. ii. p. 37) and Barthelemy (*Récueil des Cartes, &c., relatifs au Voyage du Jeune Anacharsis*, No. 27). It presents a view of the north-western side of the Acropolis, with the Propylæa to the right, the Parthenon to the left, and the colossal statue of Athena Promachos between them; whilst the grotto of Pan is represented a little to the left of the stairs which formed an ascent for foot passengers from the north side of the city to the Propylæa. Ilissus and Enneacrunos.

The far-famed Ilissus, from which Athens was principally supplied with water, and which Plato in a well-known passage of his *Phædrus* has described as a perennial stream, is now almost always dry, its waters being drawn off, either to irrigate the neighbouring gardens or to supply the artificial fountains of the modern city. It rises to the N.E. of the town, and after a course of a few miles, loses itself in the southern marshes. Not far from the supposed site of the Lyceium, and close to the walls of Athens, it is joined by another stream, or rather water-course, which is believed to be the Eridanus of Pausanias. The fountain of Callirrhoe or Enneacrunos supplied the only spring water used by the Athenians, that of the other wells being either salt or brackish. According to Thucydides, it was situated on the S. side of the city, close to the temples of Bacchus and Zeus Olympius; but other authors affirm that it rose near the stream of the Ilissus; and here, in fact, Spon and Wheler observed a fountain, a little below the south-eastern angle of the Olympeium, to which the natives still applied the name of Kalliroi. Colonel Leake says that it now forms a pool, which in the drought of summer becomes muddy and scanty, but which is still resorted to as the only place in the neighbourhood furnishing sweet water.[1]

Odeium, Eleusinium, &c.

Near the fountain of Callirrhoe or Enneacrunos stood an Odeium (which the reader will be careful to distinguish from that of Pericles, formerly mentioned), adorned with various statues of the Egyptian Ptolemies, as well as of Philip, Alexander, Lysimachus, and Pyrrhus, and probably erected by some prince of the Macedonian dynasty. This seems to have been a sort of minor theatre, intended for recitation and music without action. In Agræ, a south-eastern suburb of Athens, and on the left bank of the Ilissus, a little above Enneacrunos, was the Eleusinium, or temple of Demeter and Persephone, set apart for the celebration of the lesser Eleusinian mysteries. It is conjectured to have stood on the southern bank of the Ilissus, opposite the western point of the little island of the Ilissus, where the foundations of an ancient building are still observable. Plutarch informs us that the Stadium was erected by Lycurgus the son of Lycophron for the celebration of games during the great Panathenaic festival. Pausanias describes it as an astonishing structure, rising in the shape of an amphitheatre above the Ilissus, and extending to the banks of that stream. It was originally constructed about the year 350 B.C. for the purpose just mentioned; and about five centuries afterwards it was covered with seats of Pentelic marble by Herodes Atticus, who is said to have been interred within its walls. The marble seats have all disappeared, but the entire cavea remains, together with the masses of masonry by which the semicircular end on the south was formed out of the torrent-bed of the Ilissus; and similar ruins are also observable at the opposite end, with the piers of a bridge over the Ilissus, and the site of a building on the summit of either hill. The temple of Triptolemus, which Pausanias also places above Enneacrunos, was probably the beautiful little Ionic building which the drawings of Stuart have preserved from oblivion. It formed in his time the church of Panagia on the Rock, but has now almost entirely disappeared. Travellers have sometimes taken this building for the Eleusinium; but it is scarcely credible that the edifice where the sacred mysteries of Ceres were celebrated should have been of so small dimensions.[2]

Lyceium.

Higher up the river was Agræ, containing the temple of Artemis Agrotera, an altar dedicated to Boreas, and another sacred to the Musæ Ilissiades. In the vicinity, too, were some gardens, and a temple of Aphrodite celebrated for a statue of the goddess, executed by Alcamenes, a pupil of Phidias. But the most interesting spot in this quarter, on the outside of the walls of the city, was the Lyceium, a sacred inclosure dedicated to Apollo Lycius, where the polemarch originally held his court. It was decorated with fountains, plantations, and ornamental edifices by Peisistratus, Pericles, and Lycurgus, and became the usual place of exercise for such of the Athenian youth as devoted themselves to military pursuits. Nor was it less frequented by philosophers and others fond of retirement and study. The Lyceium is indissolubly associated with the immortal name of Aristotle, who delivered his prelections, esoteric as well as exoteric, while walking within its sacred inclosure, and whose followers, thence called Peripatetics, have added to the celebrity of the spot which formed the favourite resort of the greatest philosopher of the ancient world. The position commonly assigned to the Lyceium is on the right bank of the Ilissus, nearly opposite to the church of Petros Stauromenos, which is supposed to correspond with the temple of Artemis Agrotera, on the other side of the river.[3] We shall now proceed briefly to notice some of the remarkable places or suburbs connected with Athens.

Cynosarges.

Cynosarges was a spot consecrated to Hercules, and possessed a gymnasium, with groves frequented by the philosophers, as well as a sort of consistorial tribunal for deciding in all questions of legitimacy. After the battle of Marathon, when the city was threatened by the Persian fleet, which had doubled the promontory of Sunium (Cape Colonna), the Athenian army took up a position at Cynosarges, in order to cover the capital from attack, and to give battle to the enemy should they venture to land, which, however, they did not. Philip, the son of Demetrius, is said to have encamped on the same spot with a very different intention, and to have destroyed the groves and buildings around it, as well as those of the Lyceium. Cynosarges is supposed to have been situated at the foot of Mount Lycabettus, now the hill of St George, and to the southward of the place called Asomato.[4]

Outer Ceramicus.

On the opposite side in the west, and outside the city walls, was the exterior Ceramicus, of which we have already spoken incidentally. Here were interred Pericles, Phormio, Thrasybulus, and Chabrias; in this vast cemetery the bravest and the best men, who had proved themselves the ornaments of their country and the benefactors of their species, lay as it were in state beside that celebrated capital which their valour had defended or their genius illustrated; and, as far as the Academy, the road was lined on either side with the sepulchres of those Athenians who had fallen in battle. Over each tomb was placed a *stele* or pillar, whereon were commemorated the names and tribes of the deceased. Among the several monuments enumerated by Pausanias we may notice those of the soldiers who fought at Tanagra before the Peloponnesian war, on the Eurymedon under Cimon, at Potidæa under Callias, and at Amphipolis and Delium. One column commemorated the names of those who had fallen in Sicily; that of Nicias, however, was excepted, in consequence of his having surrendered to the enemy; while, on the other hand, Demosthenes was adjudged worthy of having his name inscribed, because, although he had capitulated for his army, he refused to be included individually in the treaty, and made an attempt on his own life. Here, also, were the cenotaphs of those who fell in the naval combat on the Hellespont, at the battle of Chæroneia, and in the course of the Lamian war; here rose the tombs of Cleisthenes, who increased the number of the Attic tribes, of Tolmides, of Conon and Timotheus, whose

Athens. exploits were only surpassed by those of Miltiades and Cimon: and here rested from their labours, in honoured repose, Zeno and Chrysippus, Harmodius and Aristogeiton, Ephialtes and Lycurgus, besides many others whom it would be tedious to enumerate. The games called Lampadephoria were celebrated in the outer Ceramicus.[1]

Academy. The Academy (of which we have already spoken under that head) was situated at the extremity of this cemetery, about six stadia from the gate Dipylum. It was originally a deserted and unhealthy spot; but it was afterwards surrounded with a wall built at a great expense by Hipparchus, and was planted, divided into walks, and supplied with fountains of water, by Cimon. Before the entrance was an altar of Love; within was a *temenos* of Athena, containing a temple of Prometheus, with an altar in the vestibule, whereon were figured in relief Hephæstus and Prometheus, and whence also the race of the Lampadephoria usually commenced. Here likewise was a sanctuary of the Muses, built by Xenophon, containing statues of the Graces, dedicated by his disciple Speusippus, and a statue of Plato by Silanion, dedicated by Mithridates, a Persian. The Academy had likewise altars of Hermes, of Hercules, and of Zeus Catæbates, also surnamed Morius, from the sacred olives called *moriæ*, which grew near the sanctuary of Athena; and contained the garden of Attalus, where the sophist Lacydes had his school, besides a βόθρος or tank, and some magnificent plane-trees of unusual height and size, which the Roman barbarian Sulla caused to be cut down during the siege of Athens. The modern name of Ahathymia leads the traveller directly to this once favourite haunt of philosophers and poets; where the divine spirit of Plato poured forth its lofty fancies and sublime speculations in a stream of eloquence which the gods themselves might envy; where genius was married to science, and poetry to philosophy; and where the foundations were laid of a school which was destined to exert a powerful and (we may add) perennial influence on the opinions of mankind. But the name is the only memorial that remains of the Academy. "It is now," says Mr Hawkins, "an open piece of ground, not exceeding five acres, and presents nothing remarkable in its appearance. A few scattered olives grow on it; and some paces farther west we saw a number of gardens and vineyards, which contained fruit trees of a more exuberant growth than in any other part of the plain."[2]

Lycabettus Another suburb was situated on the lofty height overhanging the city in the N.E., and now called the hill of St George. This hill used to be identified with one mentioned by Pausanias under the name of Anchesmus, but Mr Wordsworth in his work on Attica has very happily made out that the hill is no other than the Lycabettus, which is so often mentioned by ancient authors as in the immediate vicinity of Athens.

Long Walls. We have already had occasion to allude generally to the fortifications of Athens, including the celebrated Long Walls which connected the city with its several ports. The latter were first planned and commenced by Themistocles, after the termination of the Persian war; evidently with the intention of preventing any future invader from intercepting the communication between the City and the Peiræus, and thus starving the former into submission. But the hero of Salamis did not live to execute this great undertaking, which was continued after his death by Cimon, and finally completed by Pericles. These walls, which were deservedly considered by the ancients as one of the greatest objects of curiosity at Athens, were flanked at intervals with towers, some traces of which are still to be seen, and, together with a portion of the walls of the City and of the Peiræus at either end, formed an inclosure, which constituted one of the three great garrisons into which Athens was divided, and which, in this light, was sometimes denominated the long fortress (τὸ μακρὸν τεῖχος). From an expression of Plato, quoted by Harpocration (διαμέσου τεῖχος), as well as from the description of the Athenian fortifications given by Thucydides (ii. 13), it is perfectly evident that the City of Athens was connected with the port-towns by three walls, viz., the Phaleric, 35 stadia long, and the two long walls, each of which was 40 stadia in length. The northern long wall and the Phaleric were built first, and the intermediate one was built at the suggestion of Pericles, for the purpose of rendering the communication between Athens and Peiræus more secure. The long walls remained entire for about 54 years after their completion; that is, until the capture of Athens by the Peloponnesian forces, when they were dismantled and much injured; but 11 years subsequent to this disaster they were rebuilt by Conon, with the assistance of Pharnabazus, and the interior as well as the exterior rampart was guarded at intervals by towers and other defences. In the siege of Athens by Sulla, however, they were again broken down, and almost entirely destroyed. With regard to the existing remains, "they are chiefly remarkable," says Colonel Leake, "towards the lower end, where they were connected with the fortifications of Peiræus and Phalerum. The modern road from Athens to the port Drako, at something less than 2 miles short of the latter, comes upon the foundations of the northern long wall, which are formed of vast masses of squared stones, and are about 12 feet in thickness. Precisely parallel to it, at the distance of 550 feet, are seen the foundations of the southern long wall; the two thus forming a wide street running from the centre of the Phaleric hill, exactly in the direction of the entrance of the Acropolis."[3]

Athens.

Maritime Athens. Maritime Athens was divided into three districts and as many havens or ports; namely, Peiræus, Munychia, and Phalerum. From the earliest times Peiræus was a demus; but it did not become a harbour for ships until the administration of Themistocles; for hitherto Phalerum had been the usual port, as there the sea was nearest the city. The harbour of Peiræus was subdivided into three lesser havens, named Cantharus, Aphrodisium, and Zea. The first was appropriated as a dock-yard for the construction and repair of ships of war; the second seems to have been the middle or principal port; and the third, which was the outermost, appears from its name to have contained the granaries in which the Athenians deposited the corn imported from the countries on the Euxine and other places for the supply of the capital. The most remarkable edifices and sites in the Peiræus were the maritime bazaar or emporium called Macra Stoa, consisting of five porticoes, so connected together as to form in fact only one grand or long portico; the market-place, called Hippodameia; the Deigma or exchange: the Serangium or public bath; the Phreattys or court of criminal justice, with a sort of admiralty jurisdiction; a theatre, of which some remains are still to be seen; and, lastly, the tomb of Themistocles. The Peiræus is now known by the name of Port Drako or Leone, from a colossal figure of a lion which once stood upon the beach, but was removed by the Venetians in the year 1687. The port of Munychia, so called, it is said, from Munychus, an Orchomenian, was situated at the outer extremity of a promontory or narrow neck of land, at no great distance from the Peiræus. Strong by nature, Munychia, when inclosed within fortified lines connecting it with the other harbours, became a most important position, from the security it afforded to the maritime dependencies of Athens; and accordingly we find it always mentioned as the point which was most particularly guarded when any attack was apprehended on the seaward side. This port, which is nearly circular, is known to the

Athens. Greeks of the present day by the name of Stratioki. Phalerum, the most ancient of the Athenian ports, ceased to be of any importance in a maritime point of view after the erection of the docks in the Peiræus; but it was nevertheless inclosed within the fortifications of Themistocles, and, as we have already seen, gave its name to one of the long walls, by means of which it was connected with Athens. Its modern name is Porto Fanari.[1]

Ever since the year 1833, excavations and investigations of every kind have been carried on at Athens, partly by private enterprise and partly by the government of Greece; and the topographical discoveries which have been made within the period that has elapsed since, are very considerable; but far more numerous are the discoveries of works of art, inscriptions, and architectural remains. It would lead us too far here to give an account of all these matters, but in order to enable the reader to pursue the study of Athenian topography more in detail, we shall subjoin a list of the more important works on the subject:—1. Wordsworth, *Athens and Attica*, London, 1836; Müller, *De Munimentis Athenarum*, Göttingen, 1836; A. Westermann, in the *Neue Jahrbücher für Philologie und Paedagogik*, vol. xli., p. 230, fol. The dissertations upon the particular buildings and localities are almost countless.

Having thus completed the description of Athens, with its suburbs and dependencies, all that now remains to be done is to notice a few of the most remarkable epochs in its history, and to conclude with some account of the modern town, collected from the most recent authorities.

History of the city. The history of Athens, from the death of Alexander to the present time, may be compressed within comparatively narrow limits. Soon after the premature decease of the Macedonian hero, the citizens revolted; but they were defeated by Antipater, who garrisoned Munychia. Another insurrection followed with no better success. The garrison and oligarchy were reinstated; Demetrius, surnamed the Phalerean, was appointed governor of the city; and no less than 300 statues were erected in honour of this man, by the degenerate descendants of those Athenians who had thought a place in the foreground of a picture, painted at the public expense, an adequate reward for the victory of Marathon. But Demetrius, surnamed Poliorcetes, "the shame of Greece in peace, her thunderbolt in war," withdrew the garrison, and restored the democracy; a service for which he was deified by the Athenians, who assigned him a residence in the opisthodomos of the Parthenon, as a guest worthy of being entertained by Athena herself, and afterwards placed the Peiræus, with Munychia, at his disposal. As usual, however, they soon became weary of their idol, expelled his garrison, and regained their independence; chiefly, as is said, by the intercession of Craterus the philosopher, who persuaded Demetrius to leave them in possession of their liberty. Antigonus Gonatas, the next king of Macedonia, proved less scrupulous than "the Taker of Cities," and again seized upon Athens, where he established a garrison. But, on the death of Demetrius, son of Gonatas, the people, aided by Aratus, recovered their liberty; and the Peiræus, Munychia, Salamis, and Sunium, were restored to them, on payment of a considerable sum of money by way of equivalent. Disregarding this arrangement, however, Philip, the son of Demetrius, invaded Attica, and, encamping near the city, burned and destroyed the sepulchres and temples of the villages, slaughtered the inhabitants, and laid waste the greater part of the country.

Driven to despair by these barbarous proceedings, the Athenians were forced to solicit the protection of the Romans, which was readily granted, and to receive a garrison into the citadel, which it continued to occupy until the war with Mithridates, king of Pontus. But, taking advantage of the embarrassments of Rome, occasioned by one of the most arduous contests in which she had yet engaged, the Athenians, at the instigation of Aristion, general of the royal linguist, rose upon their protectors and expelled the garrison. This act of ingratitude met with an exemplary punishment. War was immediately declared; and Sulla soon afterwards appeared in Attica at the head of a powerful army. Unable to withstand the fury of the Romans, Archelaus, the Athenian general, relinquished the defence of the long walls, and retired into the Peiræus and Munychia. Sulla, on the other hand, immediately laid siege to the Peiræus, as well as to the city itself where Aristion commanded; and having received information that some persons had been overheard conversing in the Ceramicus, and blaming Aristion for his neglect of the avenues near the Heptachalcos, where the wall was accessible, he instantly resolved to assault the town in that quarter. Accordingly, about midnight he entered the city by the gate Dipylum, which he forced, and, having overcome every obstacle between it and the Peiraïc gate, was soon master of Athens. Aristion fled to the Acropolis; but being at length compelled to surrender from want of water, the supply of which had been cut of, he was dragged from the sanctuary of Athena, where he had sought refuge, and instantly put to death. This event took place in the year of Rome 668, or about 86 years before the Christian era. Sulla raged against the unfortunate city with the fury of a barbarian; burning the Peiræus and Munychia, defacing the monuments in the town and suburbs, and not even sparing the sepulchres of the dead in the Ceramicus.

In the civil war between Cæsar and Pompey, the Athenians declared for the champion of liberty. But although the battle of Pharsalia placed them at the mercy of Cæsar, that great and generous conqueror, "whose brow was girt with laurels more than hair," scorned to sully the lustre of his renown by any act of vengeance, and, with a magnanimity native to his character, dismissed the envoys who had been sent to propitiate him, with this fine observation: "I am content to spare the living for the sake of the dead." The same lingering affection for liberty which had led the Athenians to side with Pompey, also induced them to take part with Brutus and Cassius, in the wars of the second triumvirate; and they had even the spirit to erect statues to the two Roman patriots, beside those of their own deliverers, Harmodius and Aristogeiton. But at Philippi, as at Pharsalia, the gods declared against liberty,[2] and the Athenians were again on the losing side. Nor were they more fortunate in the contest which ensued between Octavianus and Antony; for, having joined the latter, who gave them Ægina, Cea, and other islands, they incurred the resentment of Augustus, now become master of the Roman world, who treated them with the utmost harshness and severity. Under Tiberius the city declined, but it still continued to enjoy a considerable share of freedom, and was regarded as an ally of the Romans. Germanicus conferred upon it the privilege of having a lictor to precede the magistrates; but he was censured for this act of condescension, as "the race of noble bloods" was now believed to be extinct, and the Athenian people a mixture of all nations. Nerva also proved rather indulgent to Athens; and under his successor, Trajan, Pliny exhorted Maximus, when intrusted with the government, to be mindful of the ancient glory of that classic land, and to

[1] For a full and accurate account of the present state of the Peiræus and its adjoining ports see Colonel Leake's work, p. 312, 325, and 326.

[2] The fine, though somewhat irreverent, sentiment expressed in the following line of Lucan, is not altogether inapplicable here:—
"Victrix causa diis placuit, sed victa Catoni."

Athens. rule Greece as if it had still been composed of free cities.[1] Hadrian, prouder of the archonship of Athens than of his imperial dignity, gave the city a digest of laws compiled from the codes of Draco, Solon, and other legislators, and testified his affection for it by unbounded munificence. Antoninus Pius, who succeeded Hadrian, and Antoninus the philosopher, also proved themselves benefactors of Athens, though on a less magnificent scale than their predecessor.

In the reign of Valerian, the northern barbarians first appeared in the north of Greece, where they laid siege to Thessalonica. This extraordinary apparition having alarmed all Greece, the Athenians restored their city wall, which Sulla had dismantled, and otherwise placed the town in a state of defence sufficient to secure it against a *coup-de-main*. But under Gallienus, the next emperor, Athens was besieged, and the archonship abolished; upon which the strategos or general, who had previously acted as inspector of the Agora, became the chief magistrate. Under Claudius the city was taken, but recovered soon afterwards. Constantine the Great gloried in the title of General of Athens, which had been conferred upon him, and expressed high satisfaction on obtaining from the people the honour of a statue with an inscription; a distinction which he acknowledged by sending to the city a yearly gratuity of grain. He also conferred on the governor of Attica and Athens the title of Μέγας Δοῦξ, or Grand Duke, which soon became hereditary; and his son Constans bestowed several islands on the city, in order to supply it with corn. In the time of Theodosius I., that is, towards the end of the fourth century, the Goths laid waste Thessaly and Epirus; but Theodorus, general of the Greeks, acted with so much prudence that he saved the Greek cities from pillage and the inhabitants from captivity; a service which was most gratefully acknowledged. But this deliverance proved only temporary. The fatal period was now fast approaching; and, in a real barbarian, Athens was doomed to experience a conqueror yet more savage and remorseless than Sulla. This was Alaric, king of the Goths, who, under the Emperors Arcadius and Honorius, overran both Italy and Greece; sacking, pillaging, and destroying. Never indeed did the fury even of barbarian conquest discharge itself in a fiercer or more desolating tempest. The Peloponnesian cities were overturned; Arcadia and Lacedæmon were both laid waste; the gulfs of Lepanto and Ægina were illuminated with the flames of Corinth; and the Athenian matrons were dragged in chains to satisfy the brutal desires of these rampant barbarians. The invaluable treasures of antiquity were removed; stately and magnificent structures were reduced to heaps of ruin; and Athens, stripped of the monuments of her ancient splendour, was compared by Synesius, a writer of that age, to a victim of which the body had been consumed, and the skin only remained.

After this dreadful visitation Athens sank into insignificance, and became as obscure as it had once been illustrious. We are indeed informed that the cities of Hellas were put in a state of defence by Justinian, who repaired the walls of Corinth, which had been overturned by an earthquake, and those of Athens, which had fallen into decay through age. But from the time of this emperor a chasm of nearly seven centuries ensues in its history; except that, about the year 1130, it furnished Roger, the first king of Sicily, with a number of artificers, who there introduced the culture of silk, which afterwards passed into Italy. The worms, it seems, had been brought from India to Constantinople in the reign of Justinian.

Doomed apparently to become the prey of every spoiler, Athens again emerges from oblivion in the thirteenth century, under Baldwin and his crusaders, at a time when it was besieged by a general of Theodorus Lascaris, the Greek emperor. In 1427 it was taken by Sultan Murad; but some time afterwards it was recovered from the infidels by another body of crusaders, under the Marquis of Montferrat, a powerful baron of the West, who bestowed it, along with Thebes, on Otho de la Roche, one of his principal followers. For a considerable time both cities were governed by Otho and his descendants, with the title of dukes; but being unable to maintain themselves in their Greek principality, they were at length succeeded by Walter of Brienne, who, soon after his succession, was expelled by his new subjects, aided by the Spaniards of Catalonia. The next rulers of Athens were the Acciaioli, an opulent family of Florence, in whose possession it remained until 1455, when it was taken by Omar, a general of Mahomet II., and thus fell a second time into the hands of the barbarians. The victorious sultan settled a Mahometan colony in his new conquest, which he incorporated with the Ottoman empire; and Athens, as well as Greece, continued to form an integral part of the Turkish dominions, until the treaty of Adrianople in 1829, following up the provisions and stipulations of the treaty of London, 7th July 1827, established within certain limits the new state of Greece, of which ancient Athens is now the capital.

Athens.

From the period of the Ottoman conquest to the commencement of the insurrection in 1821, Athens was only known in history by two attempts, on the part of the Venetians, to expel the Turks and make themselves masters of the city. The first of these took place in 1464, only nine years after its capture by the Osmanlis, and proved an entire failure. But the second, which was undertaken in 1687, more than two centuries later, was crowned with a temporary and fatal success. In the month of September of that year, Count Konigsmarck, a Swede in the service of Venice, having disembarked at the Peiræus a force of 8000 foot and 870 horse, forming part of the armament under Francesco Morosini, afterwards doge, marched to Athens; and having summoned the citadel without effect, he erected a battery of heavy ordnance on the hill of the Pnyx, and placing two mortars near the Latin convent at the western foot of the Acropolis, bombarded it for several days. The fire of the cannon was chiefly directed against the Propylæa, and the modern defences below that edifice; whilst the mortars continued, without intermission, to throw shells into the citadel. The consequence was, that the beautiful little temple of Nikê Apteros, the frieze of which is now in the British Museum, was completely destroyed by the breaching battery; and the Parthenon, besides being greatly injured by the bursting of the shells, was, towards the close of the attack, almost rent in pieces by the explosion of a powder magazine, which reduced the middle of the temple to a heap of ruins, threw down the whole of the wall at the eastern extremity, and precipitated to the ground every statue on the eastern pediment. The western extremity was fortunately less injured, and a part of the opisthodomos was still left standing, together with some of the lateral columns of the peristyle adjoining to the cell. But the shock was nevertheless abundantly disastrous; and when the Turks afterwards regained possession of the citadel (from which, on this occasion, they were expelled), they did all in their power to complete the destruction which the Venetians had so vigorously begun, by defacing, mutilating, or burning for lime every fragment of the edifice within their reach.[2]

Sieges.

---

1 "You will revere the gods and heroes their founders," said he; "you will respect their pristine glory, and even their age; you will honour them for the famous deeds which are truly, and even for those which are fabulously, recorded of them: remember it is Athens you approach."

2 It has been often remarked of the Turks that they are encamped rather than settled in Europe. Far from improving the countries they govern, they scathe everything that comes within their reach: they destroy monuments, but build none; and when at length

Athens || Atherston.

In the course of the late revolutionary war, Athens sustained three sieges. The first was laid by the Greeks in 1822. Having carried the town by storm, and driven the Turks into the citadel, they established a strict blockade of the fortress, which was continued until the advance of the pasha at the head of 4000 men induced them to abandon their enterprise, and fly, with the Athenians, to Salamis and Ægina. Two months afterwards, the pasha having left Athens to the defence of 1500 men, the Greeks again ventured to attack the town, and succeeded in obliging the Turks to seek refuge in the citadel, which they forthwith determined to besiege; but, from ignorance and want of means, no progress whatever was made in the operation until they obtained possession of the well which supplied the garrison with water, when the Turks agreed to capitulate upon condition of being immediately embarked with their families, and sent to Asia Minor. On various pretences, however, the embarkation was delayed from time to time; and when intelligence at length arrived that a large Turkish force was advancing upon Athens, the Palicari, instead of manning the walls and preparing for a vigorous defence, rushed in a body to the houses where the prisoners were confined, and commenced an indiscriminate massacre, in which the young and beautiful inmates of the harem, the aged and infirm, and the brave but defenceless spahis and janissaries, fell alike beneath the merciless yataghan. This atrocity, for which no possible palliation can be alleged, and which, in every circumstance of cruelty, exceeded that previously perpetrated at Trippolizza, reflects indelible dishonour on the Greek character, and proves that they inherit the faithlessness of their ancestors, with the innate ferocity of their former masters. The third siege was laid by the Turks in 1826. The Greeks had left a strong garrison in the Acropolis, with provisions for several months; and a spring of water having been discovered in the cave of Pan, and inclosed by Odysseus within the defences of the citadel, there was no danger of its being starved into a surrender. But the Turks having established batteries near the Pnyx and on the hill of the Museium, and having drawn a line of trenches round the citadel, with the view of intercepting all communication between the besieged and the Greek army, the garrison was hard pressed; and although Colonel Fabvier succeeded in forcing his way through the Turkish lines with 500 men and a supply of ammunition, and thus affording immediate relief, yet the total defeat of the Greek army under General Church, at the battle of Athens, fought in the hope of raising the siege, led soon afterwards to the surrender of the Acropolis, which remained in the hands of the Turks until the termination of the revolutionary war.

In 1812 Athens could boast of a population of 12,000 souls, but during the war the greater part of the city was laid in ruins, and most of the inhabitants were dispersed. In 1834, it was declared the capital of the new kingdom of Greece. Great exertions have been made to restore the city; streets have been opened, levelled, and widened, though most of them are still narrow, winding, and irregular; the ancient sewers have been cleaned and repaired; and the marshes of the Cephissus, the exhalations of which were extremely noxious, are in the course of being drained. The ancient buildings have also been cleared of their rubbish, and some important discoveries have been made. The small temple of Victory has already been spoken of. The other marble fragments of buildings discovered have been placed in the temple of Theseus. The royal palace is a large building of Pentelic marble, situated in the east part of the city, on the highest part of the gentle eminence which rises from the level of the Ilissus and Cephissus towards Lycabettus. A theatre, a barrack, a military hospital, the royal stables, and many large private buildings, have all been raised since 1834. The houses, built in the modern German style, are generally supplied with jalousies and balconies; and have shops and coffeehouses on the ground floor. A university was established here in 1837, and has an anatomical theatre, a considerable library, and 34 professors and teachers, with (in 1845) 195 students. The gymnasium, a preparatory school to the university, is attended by about 800 regular students, besides many more attending particular lectures. It has eight professors, divided into three classes:—1. Ancient Greek, Latin, Geometry, Algebra, Logic, and Moral Science; 2. Ancient Greek, Geometry, Algebra, Psychology, History; 3. Ancient Greek, Latin, Algebra, Geography, History, and the French and English Languages. There are also a military and an ecclesiastical academy, a normal, Lancasterian, infant, and other schools, especially one established by the American missionaries, now in a very flourishing condition, and a splendid establishment for the education of young ladies, founded by the munificence of a benevolent lady, and called the Αρσακεῖον. The population of the city in 1845 amounted to 27,800. Porto Leone (the ancient Peiræus) contained at the same date 1000 houses. A good road has been made between it and the city, a distance of five miles, and a constant communication is kept up by means of fiacres; a large customhouse, a quay, and a lazaretto, have been erected; and the port presents rather a bustling appearance. The harbour is deep and secure, but has a very narrow entrance. The government is constructing a pier, which will afford accommodation to several hundred merchant vessels. Outside, about two miles to the westward, there is a great roadstead, with nearly eighteen fathoms of water. (J. B—E.)

Athens || Atherton.

ATHENS, the name of several towns and villages in the United States of America. The principal are, 1. the capital of a county of the same name in the S.E. of the state of Ohio, finely situated on the Hockhocking River, 40 miles from its mouth. It is the seat of the Ohio university and of an academy. Pop. 1593. 2. A town in the county of Clark, state of Georgia, on the W. bank of Oconee River. Pop. 3000. It contains the university of Georgia.

ATHEROMA (*ἀθήρωμα*), in *Surgery*, an encysted tumour, containing a soft substance resembling pap (*ἀθήρη*), intermixed with hard particles.

ATHERSTON, a market-town of Warwickshire, hundred of Hemlingford, 23 miles N. of Warwick. It consists chiefly of one street, is well paved and lighted with gas; and its sanitary condition has lately been much improved by sewers, &c. It has a market-house; a parochial chapel, once part of a convent; a Roman Catholic chapel; Independent and Methodist meeting-houses; a free grammar-school; a free school for boys, and another for girls; an infant school; a literary institution; subscription library; savings bank; and a dispensary. The staple manufacture is that of hats. The Coventry canal, which passes close by the town, adds considerably to its trading facilities. Pop. in 1851, 3819.

ATHERTON, or CHOWBENT, a township in the parish of Leigh and hundred of West Derby, in Lancashire, 200 miles from London. It is one of those places which have grown to wealth and populousness since the extension of the cotton trade. Pop. in 1851, 4655.

---

they are driven out by the chances of war or revolution, the only traces they leave of their sway are to be found in the desolation with which they everywhere encompass themselves.

ATHIAS, Joseph, a celebrated rabbi and printer at Amsterdam, who printed a great number of Bibles in Hebrew, more correct than any that had previously been edited. He was a learned Hebraist as well as a skilful typographer, although it is said that there are occasional errors in the *points*, especially in the edition of 1661, many of which, however, were corrected in that of 1667. He also printed many Bibles in the corrupted Hebrew spoken by the Jews of Spain, Germany, Poland, and England. He died in 1700.

ATHLETÆ, in *Antiquity*, persons of strength and agility, disciplined to perform in the public games. The word is originally Greek, ἀθλητής, formed from ἆθλος, *certamen*, combat; whence also, ἆθλον, the prize or reward adjudged to the victor. Under athletæ were comprehended wrestlers, boxers, runners, leapers, throwers of the disk, and those practised in other exercises exhibited in the Olympic, Pythian, and other solemn games. Athletæ were first introduced at Rome by M. Fulvius in the year B.C. 186, and enjoyed under the emperors many privileges. Some curious particulars relative to their mode of training are given by several writers, which show that very different ideas were entertained, at different periods, of the diet most suitable for athletæ.—See Paus. vi.; Diog. Laërt. vi. viii.; Galen, *de Val. Tuend.* iii. *Athen.* ix. x.

ATHLONE, a market-town and parliamentary borough of Ireland, lying partly in West Meath and partly in Roscommon, 76 miles W. of Dublin. The River Shannon divides the town into two portions, which are connected by a handsome new bridge, opened in 1844. The rapids of the Shannon at this point have been obviated by means of a canal about a mile long, which renders the river navigation practicable for 71 miles above the town. In the war of 1688, the possession of Athlone was considered of the greatest importance; and it consequently sustained two sieges, the first by William III. in person, which failed; and the second by General Ginkell, who, in the face of the Irish, forded the river, and took possession of the town with the loss of only fifty men. During the late war with France, it was strongly fortified on the Roscommon side, the works covering 15 acres, and containing two magazines, an ordnance store, an armoury with 15,000 stand of arms, and barracks for 1500 men. There are two parish churches, two Roman Catholic parochial chapels, a Franciscan and Augustinian chapel, Presbyterian, Baptist, and Methodist meeting-houses, a sessions court-house, bridewell, a union workhouse, and two branch banks. It has a distillery, a brewery, and a tannery; and an active trade is carried on with Shannon harbour and Limerick by steamers, and with Dublin by the grand and royal canals. Market-days, Tuesday and Saturday. The borough returns one member to parliament. Pop. in 1851, 6218; constituency, 181.—Thom's *Irish Almanac* for 1853.

ATHOL, a district of Scotland, in the north of Perthshire, comprising an area of about 450 square miles. It is bounded on the N., the N.W., and W. by Badenoch and Lochaber in Inverness-shire, on the S. by Breadalbane and Strathmore, E. by Forfarshire, and N.E. by Mar in Aberdeenshire. This district is rough and mountainous, interspersed with woods and valleys, but withal beautiful and romantic. In Blair, amidst a wilderness of old trees, stands Blair Castle, the principal seat of the Duke of Athol. In the same neighbourhood is situated the pass of Killicrankie, memorable as being the scene of action between the troops of William III. under General M'Kay, and the Highland adherents of James II. under the celebrated Viscount Dundee. Glentilt, in this district, has lately acquired notoriety from the attempts made to deprive the public of the right of way.

ATHOS, a celebrated mountain of Chalcidice in Macedonia, situated in Long. 24. 20. E. and Lat. 40. 10. N. The ancients entertained extravagant notions concerning its height. On many accounts it was famous amongst them, but it is no less so among the moderns. The Greeks, struck with its singular situation, and the venerable appearance of its towering ascent, rising as it does in the form of an isolated pyramid, erected so many churches, monasteries, hermitages, &c., upon it, that it became in a manner inhabited by devotees, and from thence received the name of the *Holy Mountain*, which it still retains, though many of those consecrated abodes are now decayed. This mountain stands at the extremity of a peninsula of about 40 miles in length, and an average breadth of four miles. It is 6349 feet in height, about 30 miles in circumference, and may be seen 90 miles off. It abounds with many different kinds of plants and trees, particularly the pine and fir. The appearance of the mountain at present is exceedingly interesting. Upon its sides there is scattered a profusion of convents, chapels, villages, cells, and grots, inhabited by a number of monks of various countries, who never marry, and subsist on the most penitential fare. They are very industrious, cultivating the vine and the olive in the field, and practising various mechanical arts in their secluded abodes. The libraries of some of the convents appear to contain valuable remains of ancient literature; for, some years ago, a copy of the Greek fabulist Babrius was discovered there by a Greek, and editions of this collection of metrical fables have since been published in France, England, and Germany. Through this mountain, or rather through the isthmus behind it, Xerxes, king of Persia, is said to have cut a passage for his fleet when about to invade Greece. In this work he spent three whole years, employing all the forces on board his fleet. The truth of this relation was long denied, but has at length been proved. The remains, partly filled with water, were distinctly seen by Dr Sibthorp.—See Walpole's *Memoirs relating to Turkey*, 1817: *Mount Athos and its Monasteries*, 1837; and Curzon's *Monasteries of the Levant*, 1848, 2d ed.

ATHY, a market-town of Ireland, county of Kildare, 34 miles S.W. of Dublin. The town is intersected by the river Barrow, which is here crossed by a bridge of five arches. It has a church, a Roman Catholic chapel, a Presbyterian and Methodist meeting-house, court-house, jail, two banks, hospital, dispensary, barracks, &c. Adjoining the town is a small chapel, an ancient cemetery, and a small Dominican monastery. Previous to the Union it returned two members to the Irish parliament. The principal trade is in corn. Pop. in 1851, 5110.

ATIENZA, a town of Spain, in the province of Guadalajara, 21 leagues from Madrid. It stands on the declivity of a hill, contains five churches, a monastery, and about 2000 inhabitants, who are chiefly employed in agriculture and the rearing of cattle.

ATILIUS, M., an early Roman comic poet, of whose works there are no remains except a line quoted by Cicero (*ad Att.* xvi. ii.), and a few words in Varro.

ATIMIA (ἀτιμία), from α, priv. and τιμή, honour, in *Grecian Antiquity*, was an act or decree by which an offender was disgraced, and deprived of the rights of citizenship. Its rigour, however, was variously modified.

ATINA, a town of Naples, province of Terra di Lavoro, near the Melfa, and 12 miles S.E. of Sora. It has a cathedral, convent, and hospital, with about 5000 inhabitants; but it is chiefly remarkable for its remains of Cyclopean architecture.

ATKINS, or Atkyns, Sir Robert, lord chief baron of the Exchequer, was born in 1621, and educated at the university of Oxford, from whence he removed to the inns of court, and became eminent in the law. He was made knight of the bath at the coronation of King Charles II. In 1672 he was appointed one of the judges of common pleas, in which office he continued till 1679, when, foreseeing the troubles that soon afterwards ensued, he resigned his office and retired into the country. In 1689 he was made lord

Atkins || Atlantic Ocean.

chief baron of the Exchequer by King William; and about the same time held the office of speaker to the House of Lords, which had previously been refused by the Marquis of Halifax. He distinguished himself by an unshaken zeal for the laws and liberties of his country. He wrote several pieces, which have been collected into an octavo volume under the title of *Parliamentary and Political Tracts*, which afford much sound information on the true constitution of the country, and on the grounds and reasons of the Revolution. He died in 1709.

ATKINS, SIR ROBERT, son of the preceding, was born in 1646, and died in 1711. He wrote *The Ancient and Present State of Gloucestershire*, a work much esteemed.

ATKYNS, RICHARD, was born of a good family at Tuffleigh in Gloucestershire, in the year 1615. He was educated at Oxford, from whence he removed to Lincoln's Inn. During the civil wars he distinguished himself by his loyalty to King Charles I., and after the Restoration was a constant supporter of the government. Being committed to the Marshalsea prison for debt, he died there on the 14th of September 1677. He wrote a treatise *On the Original and Growth of Printing*, and several other pieces.

ATLANTES, in *Architecture*, also called Caryatides, are figures employed instead of columns to support an entablature. In general, male figures have the former, female statues the latter designation.

ATLANTIC OCEAN, one of the five great hydrographical divisions of the globe, lying between America on the W., and Europe and Africa on the E., and extending from the Arctic circle on the N., to the Antarctic circle on the S. Meridian lines from Cape Horn in South America, and from Cape Agulhas in Africa, prolonged to the Antarctic circle, complete its boundaries on the E. and W. It extends 8600 miles from N. to S., and its breadth varies from 1800 to 5400 miles, the estimated area being 25,000,000 square miles. It contains Iceland, the British Isles, the Azores, Madeira, the Canary Islands, the islands in the Gulf of Guinea, and those of the Gulf of St Lawrence, the Antilles, and Newfoundland. The principal gulfs and bays are the Bay of Biscay, and the Gulfs of Guinea, Mexico, and St Lawrence.

This ocean, according to Humboldt, presents all the indications of a valley, as if a flow of eddying waters had been directed first towards the N.E., then towards the N.W., and back again to the N.E. The parallelism of the coast north of 10° S. latitude, the projecting and receding angles, the convexity of Brazil opposite to the Gulf of Guinea, that of Africa under the same parallel with the Gulf of the Antilles, all favour this apparently speculative view. In this Atlantic valley, as is almost everywhere the case in the configuration of large continental masses, coasts deeply indented and rich in islands are situated opposite to those possessing a different character. The depth of this ocean is extremely various; and is enormous, both to the N. and S. of the equator. Thus, Captain Sir Edward Belcher, R.N., in Lat. 0. 4. N. Long. 10. 6. W., *sounded* to the depth of 3065 fathoms = 18,390 feet; Captain Barnett, R.N., in Lat. 41. 2. N. Long. 44. 3. W., sounded to the depth of 3700 fathoms, or 22,200 feet; Captain Sir James Ross, R.N., in 1840, to 2677 fathoms, or 16,062 feet; and afterwards in Lat. 33. 3. S. Long. 9. 1. E. to 4600 fathoms, or 27,600 feet; and Captain H. M. Denham, H.M.S. Herald, has obtained soundings at the vast depth of 7706 fathoms = 46,236 feet, or about 8¾ English miles. This, which is the deepest sounding ever yet taken, occurred on 30th October 1852, in Lat. 36. 49. S. Long. 37. 6. W. Two American captains have also obtained soundings at the depth of 3100 and 3500 fathoms.

The intertropical part of the Atlantic is under the influence of the trade-winds, which frequently extend to the 32d degree of N. or S. latitude. The winds blow almost invariably in the same direction, from E. to W., occasionally varying a few points to the N. or S., on the N. and S. sides of the equator. A region of calms, varying from 3 to 10 degrees of latitude, according to the season of the year, separates the two trade-winds. It is, however, daily agitated by a squall, which begins about two o'clock in the afternoon, and continues about an hour. This region does not always occupy the same part, but its central line may be placed about the 5th degree of N. latitude. In some tracts the influence of the trade-winds extends to the shores; but in general it does not come within 200 miles of the coasts.

Atlantic Ocean.

The current of this ocean first known to mariners, is called the equinoctial, and is within the tropics, especially flowing from the coast of Senegal to the Caribbean Sea. Its direction is constantly from E. to W., with a mean rapidity of 9 or 10 miles in 24 hours. This current is attributed to the impulse which is given to the surface of the sea by the trade-winds. "In the channel," says Humboldt, "which the Atlantic has dug between Guiana and Guinea on the meridian of 20 or 23 degrees, and from the 8th or 9th to the 2d or 3d degrees of N. latitude, where the trade-winds are often interrupted by winds blowing from the S. or S.S.W., the equinoctial current is more inconstant in its direction. The equinoctial current is felt, though feebly, even beyond the tropic of Cancer, in the 26th and 28th degrees of latitude. In the vast basin of the Atlantic, at 600 or 700 leagues from the coasts of Africa, vessels from Europe bound to the West Indies find their sailing accelerated before they reach the torrid zone." In the Caribbean Sea, the motion of this current is much accelerated by the action of another current. The Mozambique current, flowing from N. to S. between Madagascar and the eastern coast of Africa, bends to the north of the Lagullas bank, round the southern point of Africa, and advances with much violence along its western coast beyond the equator to the island of St Thomas. It gives a north-westerly direction to a portion of the waters of the South Atlantic, causing them to strike Cape St Augustin, and to follow the shores of Guiana beyond the mouth of the Orinoco, the Boca del Drago, and the coast of Paria. The coast of America presenting a barrier to the equinoctial current; its waters are driven with velocity through the strait formed by Cape Catoche and Cape St Antonio, into the Gulf of Mexico; and after following the bendings of the coast, force their way back into the open sea N. of the Straits of Bahama, where it forms a warm rapid current, known as the Gulf Stream. At first its rapidity is sometimes as great as five miles an hour, but it decreases as it proceeds towards the north, at the same time that its breadth increases and its waters become cool. Between Cayo Biscaino and the bank of Bahama the breadth is only 15 leagues, while in the latitude of 28½ degrees it is 17; and in the parallel of Charlestown, opposite Cape Henlopen, from 40 to 50 leagues. "The waters of the Mexican Gulf forcibly drawn to N.E. preserve their warm temperature to such a point, that in 40 and 41 degrees of latitude I found them at 22·5° cent. (= 72·4° Fahr.) when out of the current; the heat of the ocean at its surface was scarcely 17·5° (= 63·5° Fahr.) In the parallel of New York and Oporto, the temperature of the Gulf Stream is consequently equal to that of the seas of the tropics in the 18th degree of latitude, as, for instance, in the parallel of Porto Rico and the islands of Cape Verd."—(*Humboldt.*) In Lat. 41. 25. and Long. 67., where it is nearly 80 leagues broad, it turns suddenly to the E., and almost touches the southern edge of the Great Newfoundland Bank, from whence it continues its course E. and E.S.E. to the Azores. On the meridian of Corvo and Flores, the most westerly islands of the Azores group, the breadth of the current is 180 leagues. From the Azores it turns towards the Straits of Gibraltar, the island of Madeira, and the Canary group. There are several other minor currents in this vast ocean, as the branch

sent off by the Gulf Stream before reaching the Western Azores, which at certain seasons of the year flows towards Ireland and Norway. The experiments of Sir James Ross and Captain Denham show that, after the depth of 200 or 300 fathoms, the temperature of the Atlantic waters is stationary at 40° Fahr., whatever be the temperature at the surface. This uniformity of temperature in the waters of great oceans renders them the means of mitigating the extremes of tropical and polar regions.—See Rennell's *Investigation of the Currents of the Atlantic Ocean;* Humboldt's *Cosmos, Personal Narrative, &c.*

ATLANTIDES, in *Astronomy*, a denomination given to the Pleiades, or seven stars, sometimes also called *Vergiliæ*. They are thus called, as being supposed by the poets to have been the daughters either of Atlas or his brother Hesperus, who were translated into heaven.

ATLANTIS, Atalantis, or Atlantica, an island mentioned by Plato and some others of the ancients, concerning the real existence of which many disputes have been raised. Homer, Horace, and the other poets make two Atlanticas, calling them *Hesperides* and *Elysian Fields*, and representing them as the habitations of the blessed. The most distinct account of this island we have is in Plato's *Timæus*, of which Mr Chambers gives the following abridgment:—"The Atlantis was a large island in the Western Ocean, situated before or opposite to the Straits of Gades. Out of this island there was an easy passage into some others, which lay near a large continent, exceeding in size all Europe and Asia. Neptune settled in this island (from whose son Atlas its name was derived), and divided it amongst his ten sons. To the youngest fell the extremity of the island, called *Gadir*, which, in the language of the country, signifies *fertile*, or *abundant in sheep*. The descendants of Neptune reigned here, from father to son for a great number of generations, in the order of primogeniture, during the space of 9000 years. They also possessed several other islands; and passing into Europe and Africa, they subdued all Libya as far as Egypt, and all Europe to Asia Minor. At length the island sunk under water; and for a long time afterwards the sea thereabouts was full of rocks and shelves." Many of the moderns also are of opinion that the existence of the Atlantis is not to be looked upon as entirely fabulous. Some take it to have been America; and on this supposition, as well as from a passage in Seneca's *Medea*, and other obscure hints, they imagine that the new world was not unknown to the ancients. But allowing this to be the case, the abovementioned continent, which was said to lie beyond Atlantis, would seem rather to have been the continent of America than Atlantis itself. The learned Rudbeck, professor in the university of Upsal, in a work entitled *Atlantica sive Manheim*, endeavours to prove that Sweden and Norway are the Atlantis of the ancients; but the situation assigned to it renders this notion untenable. Kircher supposes it to have been an island extending from the Canaries quite to the Azores; adding, that it was really swallowed up by the ocean, as Plato asserts, and that these small islands are the shattered remains of it which were left standing.

The New Atlantis is the title of the interesting fragment in which Lord Bacon has sketched an ideal or scientific commonwealth.

ATLAS, king of Mauritania, is supposed to have been contemporary with Moses. From his taking observations of the stars on a mountain top, the poets represented him as turned into the mountain which bore his name, and sustaining the heavens on his shoulders. Being an excellent astronomer, and the first who taught the doctrine of the sphere, they tell us that his daughters were turned into stars; seven of them forming the Pleiades, and other seven the Hyades. A good account of Atlas, under his different aspects, may be found in Smith's *Dictionary of Greek and Roman Biography and Mythology*, vol. i.

Atlas, a celebrated but little known mountain chain of Northern Africa, between the great desert of Sahara and the Mediterranean. Geographers differ as to the extent of this range, some considering it to extend from Cape Ghir on the Atlantic to Cape Bon, the north-east point of Tunis; while others, under that name, include the whole mountain system between Cape Nun and the greater Syrtis. In this latter sense it forms the mountain-land of the countries of Marocco, Algeria, Tunis, and Tripoli. It is composed of ranges and groups of mountains, inclosing well-watered and fertile valleys and plains, and having a general direction from W. to E. The highest peaks are supposed to attain an elevation of nearly 15,000 feet; and although none of them reach the height of perpetual snow, some of their loftiest summits are covered with snow during the greatest part of the year. Mount Miltsin, 27 miles S.E. of the city of Marocco, was ascertained by Captain Washington to be 11,400 feet high. The greatest heights are in Marocco, from which point they appear to diminish in elevation as they extend towards the E. These mountains, except the loftier summits, are, for the most part, covered with thick forests of pine, oak, cork, white poplar, wild olive, and other trees. The inferior ranges seem to be principally composed of secondary limestone, which, at a greater elevation, is succeeded by micaceous schist and quartz-rock; and the higher chains are said to consist of granite, gneiss, mica-slate and clay-slate. The secondary and tertiary formations are frequently disturbed and upraised by trap-rocks of comparatively modern date. Lead, iron, copper, antimony, and sulphur, occur frequently here; and in the Marocco portion of the range, mines of gold and silver are said to exist. In the Algerian division are mines of copper, lead, silver, and antimony.

Atlas, in *Literature*, a collection of maps, charts, or other tables; so called from the fabulous king of that name, who is sometimes represented as supporting the world on his shoulders. The term was first used in this sense by the celebrated geographer Mercator, in the sixteenth century.

Atlas, in *Anatomy*, the first or uppermost vertebra in the neck, so called from its supporting the head. See Anatomy.

Atlas, a kind of Eastern silk.

ATMOMETER (from ἀτμός, *vapour*, and μετρόν, *a measure*), an instrument contrived by Professor Leslie, for measuring the quantity of moisture exhaled from any humid surface in a given time. It consists of a very thin ball of porous earthenware, from one to three inches in diameter, having a small neck firmly cemented to a long and rather wide tube of glass, to which is adapted a brass cap, with a narrow collar of leather to fit close. Being filled with distilled or pure water, the waste and descent of this column serves to indicate the quantity of evaporation from the external surface of the ball. The tube is marked downwards, through its whole length, by the point of a diamond, with divisions across it, amounting to from 200 to 500, each of which corresponds to a ring of fluid, that, spread over the whole exhaling surface, would form a film only one thousandth part of an inch in thickness. This graduation is performed by previously sealing one of the ends of the tube with wax, and introducing successive portions of quicksilver, to mark every 20, 50, or 100 of those divisions; being calculated of equal bulk to disks of water, that have the surface of the ball (exclusive of the neck) for their base, and so many thousand parts of an inch for their altitude.

The instrument, being thus constructed, has its cavity filled with pure water, and its cap screwed tight, and is then suspended freely out of doors, sheltered indeed from rain, but exposed to the action of the wind. The water transudes through the porous substance of the ball just as fast as it evaporates from the external surface; and

Atmometer.

this waste is measured by the corresponding descent of the liquid in the stem. At the same time, the column is suspended in consequence of the tightness of the cap, and prevented from oozing so freely as to drop from the ball. As the process of evaporation goes on, minute globules of air, separated by the removal of atmospheric pressure from the body of the water, or partly introduced by external absorption, continue to rise in fine streamlets to the top, where they partially occupy the space left by the subsidence of the fluid column. We need scarcely observe, that, after the water has sunk to the bottom of the stem, it will be requisite again to fill the cavity.

It is a fact of main importance for the accuracy of the atmometer, that the rate of evaporation is nowise affected by the quality of the porous ball, and continues precisely the same whether the exhaling surface appears almost dry or glistens with excess of moisture. This rate must evidently depend on the effect of the dryness of the air combined with its quickness of circulation. In a close room the instrument might therefore serve the purpose of an hygrometer; and, placed out of doors, first screened, perhaps, for an hour, and then exposed during an equal space of time, it would furnish data for calculating the velocity of the wind.

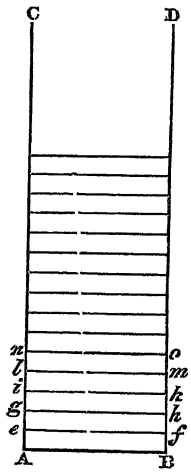
This instrument is of extensive application and great practical utility. To ascertain readily and accurately the rate of evaporation from any surface, is an important acquisition, not only in meteorology, but in agriculture, and in the various mechanical arts. The quantity of exhalation from the surface of the ground is not of less consequence than the measure of the fall of rain, and a knowledge of it might often direct the farmer advantageously in his operations. On the rapid dispersion of moisture depends the efficacy of drying-houses, which are generally constructed on most erroneous principles.

The atmometer, in its most compendious form, is admirably fitted for delicate experiments on the evaporation which takes place in close vessels when absorbent substances are introduced. Let the ball of the instrument, for example, be immersed in air variously rarefied or condensed, under a receiver covering a surface of sulphuric acid which has different degrees of strength; and, things being thus disposed, on extracting the common air, and introducing hydrogen gas, the rate of evaporation will then be nearly tripled.

We shall close this notice with mentioning a striking fact, which shows the necessity of extreme caution in all physical inquiries. Let the ball of an atmometer be cemented to a narrow glass tube of three or four feet in length, and the whole capacity filled with fresh distilled water. Now invert the instrument upright in a basin of quicksilver, and secure it in that situation; the quicksilver, following the column of water, will rise at first quickly, and then by degrees more slowly, till it reaches, perhaps, an elevation of 28 inches, where it will remain stationary and afterwards sink down, when the evaporation is nearly spent. Ice-water is raised in this way about 26 inches only, and common water scarcely 24 inches; the air separated from such liquids forming near the top of the ball a thin medium, which, by its elasticity, counteracts in part the pressure of the external atmosphere supporting the mercurial column. But a similar experiment, where the shoot of a vine was cemented to a tube holding quicksilver, has been thought, by Dr Hales and M. Du Hamel, quite conclusive in proving the *power* of the living principle of vegetation. It is obvious that the force of evaporation alone was sufficient to explain the facts advanced by those ingenious philosophers. See METEOROLOGY.

(J. L.)

Atmosphere.



ATMOSPHERE is the name applied to the invisible elastic medium which surrounds the globe of the earth to an unknown height. The fluid of which it is composed is usually distinguished by the name of *air*.

It is well known that the pressure of the atmosphere is the cause of the rise of the mercury in the barometer. Now the mean height of the barometer at the level of the sea is 29·82 inches. Hence it follows that the whole weight of the atmosphere is equal to that of a sphere of mercury covering the whole surface of the globe, and extending to the height of 29·82 inches. The specific gravity of mercury is 13·568, and a cubic inch of water at the temperature of 60° weighs very nearly 252·5 grains. Hence a cubic inch of mercury will weigh 3425·92 grains, or 0·48956 lb. avoirdupois; and a column of the atmosphere reaching from the surface of the earth to the utmost height to which that elastic fluid reaches, and whose base is a square inch, weighs about 14·6 lbs. avoirdupois, or exerts a pressure equal to 14·6 lbs. upon the earth or any substance on which it rests.

The atmosphere consists chiefly of *air*, an elastic fluid composed of a mixture of four volumes of azotic with one volume of oxygen gas. Now, from the most exact experiments hitherto made, it follows, that at the temperature of 60°, and under the mean pressure of the atmosphere, a cubic inch of air weighs 0·311446 grains. If, therefore, the air were everywhere of the same density, the height of the atmosphere above the surface of the earth would be 328,021 inches, or 27,335 feet, or 5·17 miles.

Density of the atmosphere.

But air is an elastic fluid, the particles of which repel each other with a force varying inversely as the distance of the centres of the particles from each other. It is obvious, from this property of air, that its volume, and consequently its density, will depend upon the pressure. The greater the pressure, the smaller the volume. Those portions of the atmosphere that are in contact with the earth are pressed upon by the whole portion above them. The air at the top of a mountain is pressed upon by all the air above it; while all that portion below it, or lying between the top of the mountain and the surface of the sea, exerts no action on it whatever. This will be better understood by the following diagram. Let ABCD be conceived to be a section of a vessel extending from the surface of the earth at AB to the limit of the atmosphere CD, and filled with air. Let this pillar of air be divided into an infinite number of equal sections, each exceedingly thin, by the planes *ef*, *gh*, *ik*, *lm*, *no*, &c. Since the density of air is always as the compressing force, it follows that the density of the stratum AB*ef* is to that of the density of the stratum *efgh* as *ef*CD to *gh*CD. So that the difference between the pressures on *ef* and *gh* is equal to the quantity of air *efgh*. For the same reason, the difference between the pressures on *gh* and *ik* is equal to the quantity of air *ghik*; and this ratio holds to the very limit of the atmosphere. Therefore the densities of air in these spaces are proportional to the quantities of which they themselves are the differences. Now, when there is a series of quantities whose terms are proportional to their own differences, both those quantities and their differences are in geometrical progression; therefore the densities of the strata of air AB*ef*, *efgh*, *ghik*, *iklm*, &c. are in geometrical progression.

It is equally obvious that the heights of these equal spaces above AB, the surface of the earth, are in arithme-

Atmosphere.

tical progression. If *ef* be 1 inch above the earth's surface, *gh* will be 2 inches, *ik* will be 3 inches, and so on. From all this we derive this remarkable conclusion, that *if the altitudes above the surface of the earth be taken in arithmetical progression, the densities of the air at these altitudes will be in geometrical progression decreasing.* If at a certain altitude above the earth's surface the density of the air be one half what it is at the surface of the earth, then at twice that altitude the density will be reduced to one fourth of the density at the earth's surface, and so on.

We can calculate the density of the atmosphere at all heights above the earth's surface very readily by means of a table of logarithms; for logarithms constitute a set of numbers in arithmetical progression annexed to another set of numbers which are in geometrical progression. If, therefore, we take logarithms to represent the heights, the numbers to which these logarithms are attached will represent the corresponding densities of the air. Suppose the density of the air at one mile above the surface of the earth to be represented by unity; then, from the common tables of logarithms, we easily deduce the following densities at greater heights:

Height.	Density.
1 mile	1·
2	0·7943
3	0·6309
4	0·5011
5	0·3981
6	0·3163
7	0·2511
8	0·1995
9	0·1585
10	0·1260

So that at 10 miles the density of the air is only $\frac{1}{8}$th of its density at one mile above the surface of the earth.

Its height.

These observations are sufficient to show that the height of the atmosphere above the surface of the earth must greatly exceed five miles; but how much, we have no data to enable us to determine.

Air possesses the property of refracting light; that is, of bending it from a right line, and making it move in a curve. The consequence of this property is, that the sun continues visible for some little time after he sets, and is seen also a short time before he rises. Nor are we deprived of all the benefits of his rays so long as any of them are capable of reaching the utmost limit of the atmosphere. This light, brought to the surface of the earth by the refracting power of the atmosphere, is called *twilight;* and mathematicians have endeavoured to determine the height of the atmosphere by observing how many degrees below the horizon the sun must sink before twilight ends. The result of this calculation is, that, at the height of 45 miles, the atmosphere has no sensible power of refracting light. Its rarity therefore at that height must be very great.

There is another way in which an estimate may be formed of the height of the atmosphere. That height must ultimately depend upon the degree of rarity which air is capable of bearing. The particles of air repel each other with forces varying inversely as the distances of the centres of these particles from each other. Now there is no great difficulty in rarefying air by means of a good air-pump, till it is capable of supporting a column of mercury only $\frac{1}{10}$th of an inch in height. In such a case air is rarefied about 300 times, and the distance between the centres of its particles is increased seven times; consequently the force of repulsion between these particles is reduced to $\frac{1}{7}$th of what it is when air is of its mean density. If we suppose that this is the utmost limit to the rarefaction of air (a supposition not at all likely to be strictly true), we are entitled to infer that the atmosphere extends to the height of 40 miles, with properties yet unimpaired by extreme rarefaction.

Atmosphere.

If matter be infinitely divisible, the extent of the atmosphere must be equally infinite. But if air consists of ultimate atoms no longer divisible, then must the expansion of the medium composed of them cease at that distance where the force of gravity downwards upon a single particle is equal to the resisting force arising from the repulsive force of the particles. If the air be composed of indivisible atoms, our atmosphere may be conceived to be a medium of finite extent, and may be peculiar to our planet; but if we adopt the hypothesis of the infinite divisibility of matter, we must suppose the same medium to pervade all space, where it would not be in equilibrio, unless the sun, the moon, and all the planets, possess their respective shares of it condensed around them, in degrees depending on the force of their respective attractions.

Has a limit.

It is obvious that the atmosphere of the moon (supposing it to have any) could not be perceived by us; for, since the density of an atmosphere of infinite divisibility at her surface would depend upon the force of her gravitation at that point, it would not be greater than that of our atmosphere when the earth's attraction is equal to that of the moon at her surface. Now this takes place at about 5000 miles from the earth's surface,—a height at which our atmosphere, supposing it to extend so far, would be quite insensible.

But since Jupiter is fully 309 times greater than the earth, the distance at which his action is equal to gravity must be as $\sqrt{309}$, or about 17·6 times the earth's radius; and since his diameter is nearly 11 times greater than that of the earth, $\frac{17{\cdot}6}{11} = 1{\cdot}6$ times his own radius will be the distance from his centre at which an atmosphere equal to our own should occasion a refraction exceeding 1°. To the fourth satellite this distance would subtend an angle of about 3° 37′; so that an increase of density to $3\frac{1}{2}$ times our common atmosphere would be more than sufficient to render the fourth satellite visible to us when behind the centre of the planet, and consequently to make it appear on both sides at the same time. It is needless to say that this does not happen, and that the approach of the satellites, instead of being retarded by refraction, is regular till they appear in actual contact; showing that there is not that extent of atmosphere which Jupiter should attract to himself from an infinitely divisible medium filling space.

If the mass of the sun be considered as 330,000 times that of the earth, the distance at which his force is equal to gravitation will be $\sqrt{330{,}000}$, or about 575 times the earth's radius; and if his radius be 111·5 times that of the earth, then this distance will be $\frac{575}{111{\cdot}5} = 5{\cdot}15$ times the sun's radius. But Dr Wollaston has shown, by the phenomena attending the passage of Venus very near the sun on the 23d May 1821, that the sun has no sensible atmosphere. For the apparent and calculated place of that planet were the same when the planet was only 53′ 15″ from the sun's centre. M. Vidal of Montpellier observed Venus on the 30th May 1805, when her distance from the centre of the sun was only 46′ of space; and the apparent and calculated positions of that planet corresponded. These observations leave no doubt that the sun has no sensible atmosphere, and of course are inconsistent with the notion of the infinite divisibility of the matter of our atmosphere.

Atmosphere. But if air consist of atoms incapable of further division, it is obvious that the height of the atmosphere has a limit, and that limit is the place where the gravitation of the atoms of air just balance the force of their repulsion. The exact situation of this limit we cannot assign; but it cannot far exceed the height of 45 miles above the earth's surface. Nor are the objections to this determination drawn from meteors of sufficient weight to overturn the force of the arguments just adduced. Dr Halley observed a meteor in the month of May 1719, whose altitude he computed to be between 69 and 73½ English miles, its diameter 2800 yards, and its velocity about 350 miles in a minute. The celebrated meteor which appeared on the 18th August 1783 was not less than 90 miles above the surface of the earth. Its diameter must have been at least equal to that of Dr Halley's meteor, and its velocity certainly not less than 1000 miles in a minute. We know too little about the nature of these meteors to connect them with the earth's atmosphere. Indeed their velocity would lead to the conclusion that they were revolving round the earth like satellites. The light which they emitted, or the state of combustion which they exhibited, we cannot explain. But the same difficulty occurs to account for the volcanoes which have been seen in the moon, though we are quite certain that her atmosphere is far too rare to support combustion.

About 45 miles high.

Air a mixture of two gases, The ancients thought that air constituted one of the four *elements*, from which, in their opinion, all things originated; and this doctrine continued prevalent till after the year 1774. It was during that year that Dr Priestley first discovered oxygen gas, and showed it to be a constituent of air. He determined several of its most remarkable properties, and called it *dephlogisticated air*, from a notion he entertained that it was air deprived of *phlogiston*.

oxygen and azotic, When *azotic* gas, the other constituent of air, was discovered soon after, the difference between its properties and those of oxygen gas could not fail to strike the most careless observer. Bodies burn more rapidly, with much greater splendour, and with the evolution of much greater heat, in oxygen gas than they do in common air; while in azotic gas they cannot be made to burn at all. Animals breathe oxygen gas without inconvenience, and they live much longer when confined in a given bulk of it, than when in the same volume of common air; but in azotic gas animals cannot live at all. When plunged into it they die of suffocation, precisely as they would do if plunged under water. Dr Priestley considered *oxygen* gas as the pure elementary principle of the ancients: common air was oxygen united to a certain quantity of phlogiston, while azotic gas was oxygen saturated with phlogiston.

Scheele discovered both oxygen and azotic gas, without any knowledge of what had been done in Britain; and he first drew the proper consequences from his experiments. Air, in his opinion, consists essentially of a mixture of two distinct elastic fluids, namely, oxygen and azote. He determined the properties of each, and made a set of experiments to ascertain the relative volumes of each contained in the atmosphere. The result of these experiments led him to the conclusion that air is a mixture of

27 volumes oxygen gas,
73 volumes azotic gas.

100.

Lavoisier drew the same conclusions as Scheele had done; and he assures us that he did so before he knew any thing of the researches and discoveries of the Swedish chemist; and, what is very remarkable, he deduced the same volumes of each gas, as constituents of the atmosphere, as Scheele had done. His experiments were made in the same way as Scheele's, and no doubt the mistakes of both had the same origin. Atmosphere.

It was in 1782 that Mr Cavendish, by a careful analysis of the air in the neighbourhood of London, repeated frequently, and continued for a whole year, determined that the volume of oxygen gas in atmospherical air is a good deal smaller than Scheele and Lavoisier had made it. He found the constituents of air to be—

79·18 volumes of azote,
20·82 volumes of oxygen.

100·00.

He found that these proportions never varied, though he analyzed air at different periods of the day, and during all the different seasons of the year. Hence it followed that the conclusions drawn by Dr Ingenhousz and others, that air differs in the proportion of oxygen gas which it contains in different parts of the earth, and that the salubrity of different places is connected with this difference, were erroneous.

These experiments of Mr Cavendish were published in the *Philosophical Transactions* for 1783; but they continued for many years unattended to. The determination of Scheele and Lavoisier was universally adopted; and the notion of Dr Ingenhousz, that the proportions between the oxygen and the azote vary in different places, was also adopted. At last, in 1802, Berthollet announced that he had frequently analyzed the air in Egypt, by absorbing its oxygen by means of a stick of phosphorus, and that he had always found it a compound of

79 volumes azote,
21 volumes oxygen.

100.

Davy about the same time announced that he had tried air from the coast of Africa, from Cornwall, and from the neighbourhood of Bristol, and had uniformly found it composed of 79 volumes of azotic gas and 21 volumes of oxygen gas. It was soon after analyzed in Edinburgh, in North America, and in France, with the very same results. Gay-Lussac and Humboldt made a set of careful experiments to determine the exact proportions of the two constituents, and confirmed the ratio of 21 volumes of oxygen gas and 79 volumes of azotic gas. This ratio has been generally adopted by chemists.

in the proportion of 80 vol. azote to 20 vol. oxygen. But there is a circumstance which cannot avoid striking an attentive observer; namely, the very near approach of these numbers to 80 volumes azotic and 20 volumes oxygen gas, or four volumes azotic and one volume oxygen gas. It has been deduced from a great variety of unexceptionable experiments, that a volume of azotic gas is equivalent to an atom, while half a volume of oxygen gas is equivalent to an atom. Hence four volumes azotic and one volume oxygen gases are equivalent to four atoms azote and two atoms oxygen, or to two atoms azote and one atom oxygen. If, therefore, we were to admit that air consists of 80 volumes azotic and 20 volumes of oxygen gases, it would follow that it is a compound of two atoms azote and one atom oxygen. There is no evidence, indeed, that in air the oxygen and azotic gases are chemically combined; the phenomena of air rather lead to the conclusion that the two elastic fluids are merely mixed. And the hypothesis of Dalton, that the particles of elastic fluids only repel particles of their own kind, but that two elastic fluids are not mutually elastic to each other, will enable us to account for their remaining intimately mixed, though not chemically united.

It may seem immaterial, then, whether air be a mixture of azotic and oxygen gases in the proportion of two atoms of the former to one atom of the latter, or in the pro-

Atmosphere.

portion (as chemists at present think) of 1·975 atom azote and 1·05 atom oxygen; or, as fractions of atoms can hardly be admitted, of 79 atoms of azote and 42 atoms of oxygen. But certainly the constitution of air must appear much simpler, and therefore much more agreeable to contemplate, when viewed as consisting of the simple ratio of two to one, than in the much more complex ratio of 79 to 42. The writer of this article was induced in consequence to make a set of experiments with all possible attention to accuracy, in order to deduce the volume of oxygen gas which it contains. The air was collected in a grass field at some distance from houses and trees; and this spot was selected as likely to furnish air containing as great a proportion of oxygen as it ever contains, because grass and vegetables in general are supposed to make up the waste of oxygen which the air sustains by the processes of combustion and respiration,[1] and because the quantity of carbonic acid which it was likely to contain would be too small to make any sensible alteration in the experiments.

Ten measured volumes of this air were placed successively in a small glass jar, over mercury, together with a stick of phosphorus. After the oxygen gas had been removed by the phosphorus, the air was washed, and then measured. The following table exhibits the result of these ten trials. 100 volumes of air consist of

	Volumes of Azotic Gas.	Volumes of Oxygen Gas.
1	80·927	19·073
2	79·246	20·754
3	80·504	19·496
4	79·532	20·468
5	79·851	20·149
6	79·652	20·348
7	79·374	20·626
8	80·770	19·230
9	79·843	20·157
10	80·028	19·972
Mean,	79·9735,	20·0265

The mean of these ten trials gives us air, a mixture of 79·9735 volumes of azotic and 20·0265 volumes of oxygen gas. Now, this approaches as near 80 volumes of azotic and 20 volumes of oxygen gas as the mode of experimenting permitted, for the measure employed to determine the volume of the gases was about half an inch in diameter.

It was found, also, that when 100 volumes of air were mixed with 42 volumes of hydrogen gas, and an electric spark passed through the mixture, the diminution of bulk by the explosion was precisely 60 volumes; and this in three successive experiments. Now, this diminution is owing to the oxygen of the air uniting with the hydrogen gas and forming water, and water is a compound of two volumes hydrogen and one volume oxygen gas. The third part of the diminution, therefore, gives us the quantity of oxygen gas consumed. Now, the third of 60 is 20, which constitutes therefore the volumes of oxygen gas in 100 volumes of air.

If we employ less than 42 volumes of hydrogen gas, the whole oxygen of the air is not consumed. Thus, when we employ a mixture of 100 volumes of air and 40 volumes of hydrogen gas, the diminution of volume after combustion is only 57 volumes, which would indicate 19 volumes of oxygen instead of 20 in the air; so that one volume of oxygen in this case has escaped combustion. When we mix more hydrogen than 42 volumes with 100 volumes of common air, the diminution of volume is somewhat greater than 60, and it goes on increasing slowly till the volume of hydrogen gas is equal to that of the air. 100 volumes of air being mixed with 100 volumes of hydrogen gas, and fired, the diminution amounted to 64 volumes. This would raise the amount of the oxygen in 100 volumes of air to $21\frac{1}{3}$ volumes.

Atmosphere.

It is obvious from these experiments that absolute certainty cannot be obtained by firing mixtures of air and hydrogen gas. The reason, doubtless, is, that when the surplus of hydrogen is considerable, a little of it unites with the azotic gas of the air, and forms ammonia, which, being absorbed by the water over which the explosion is made, occasions a greater diminution of bulk than would have proceeded from the simple union of all the oxygen of the air with hydrogen gas.

Specific gravity of these two gases.

Knowing the composition of air to be 80 volumes azotic and 20 volumes oxygen gas, and knowing the atomic weight of these bodies to be azote 1·75 and oxygen 1, we can easily deduce the specific gravity of azotic and oxygen gases, reckoning that of air unity, in the following manner:—

100 parts of air by weight must be a compound of

oxygen $22{\cdot}2\dot{2}=a$,

azote $77{\cdot}7\dot{7}=b$.

Let x=specific gravity of oxygen gas,

y=specific gravity of azotic gas,

$$\frac{x+4y}{5}=1 \text{ and } x=5-4y$$

$$x:4y::a:b \text{ and } x=\frac{4ay}{b}.$$

Hence $5-4y=\frac{4ay}{b}$, from which we deduce

$$y=\frac{5b}{4a+4b}=\frac{5\times 77{\cdot}7\dot{7}}{4\times 22{\cdot}22+4\times 77{\cdot}7\dot{7}}=0{\cdot}9722\dot{}$$

and $x=5-4y=5-3{\cdot}888\dot{8}=1{\cdot}111\dot{1}$.

Thus, the specific gravity of these two gases is as follows:—

oxygen gas.....1·111$\dot{1}$,

azotic gas.....0·9722$\dot{}$.

That the specific gravity of these two gases hitherto determined by the most careful experimenters is inaccurate, is obvious from this, that when we calculate the specific gravity of air from them, it never comes out unity, but usually higher than unity.

Air contains carbonic acid.

Besides oxygen and azotic gases, air contains likewise a little carbonic acid gas. Who first made that remark we do not know; but it could not avoid being inferred as soon as the cause of the difference between caustic and mild alkali came to be known. Chemists at first stated the volume of carbonic acid gas in the atmosphere at 1 per cent., but this determination was not founded on any accurate experiments. Mr Dalton found the quantity much smaller than had been stated by preceding experimenters. He observed, that if a glass vessel, filled with 102,400 grains of rain water, be emptied in the open air, and 125 grains of lime water poured in, and the mouth then closed, by sufficient time and agitation the whole of the lime water is just saturated with the carbonic acid which it finds in the inclosed volume of air; but 125 mea-

[1] It is easy to show, that whether the oxygen thus withdrawn from the air be supplied or not, no alteration in the proportions of the constituents amounting to one millionth part can possibly have taken place. It would therefore be quite insensible as far as our means of estimating it can go.

Atmosphere.

sures of lime water require 70 measures of carbonic acid gas to saturate them. Hence it follows that 10,000 volumes of air contain 6·8 volumes of carbonic acid.[1] Thenard ascertained by means of barytes water that 10,000 volumes of air which he examined contained 3·91 volumes of carbonic acid.[2] This is little more than half the quantity found by Mr Dalton. But by far the most complete set of experiments on the volume of carbonic acid gas in the atmosphere was made by M. Saussure. He abstracted the carbonic acid from given volumes of air by means of barytes water. The carbonic acid was estimated by dissolving the precipitated carbonate of barytes in muriatic acid, and throwing down the barytes in the state of sulphate from the solution. The sulphate of barytes, ignited and weighed, easily furnished the weight of carbonic acid; and this weight, together with the known specific gravity of carbonic acid gas, furnished the data for determining its volume. The experiments were continued for two years. Sometimes (indeed most commonly) the air examined was collected at Chambeisy, a meadow about three fourths of a league from Geneva, elevated about 52½ feet above the lake, and distant from it 820 feet. Its elevation above the level of the sea is 1272 feet. It is dry, open, and consists of a clay soil, a little inclined. The mean quantity of carbonic acid gas found in 10,000 volumes of air deduced from 104 observations made during both day and night, and at all seasons, was 4·15 volumes. The greatest quantity was 5·74 volumes, and the smallest 3·13 volumes. The quantity of this gas is affected by rainy weather; for when the soil is soaked with water, it has the property of imbibing this gas. Hence in rainy seasons the quantity of carbonic acid gas in the atmosphere is usually rather less than in dry seasons. On the contrary, it would seem, from the observations of Saussure, that a continued frost has a tendency to augment the quantity of carbonic acid in the atmosphere, doubtless because the frozen and dry soil does not possess the property of absorbing it.

Air taken from the surface of the lake of Geneva, at an elevation of four feet, was found in general to contain less carbonic acid than the air of Chambeisy; but the same kind of variation, depending on the season of the year, was observable in both. Air from the streets of Geneva, on the contrary, was found rather more loaded with carbonic acid than the air above Chambeisy; but the difference was not great. The volume of carbonic acid in air from the tops of mountains was found to be rather greater than that of carbonic acid in air from the low country; and this difference is more remarkable in rainy than in dry weather.

Wind has rather a tendency to augment the quantity of carbonic acid in the air in low situations, doubtless by mixing together the air on the mountains and in the valleys; but the difference is so small that it only becomes perceptible by a long series of observations.

In general, the air over plains contains a greater proportion of carbonic acid during the night than during the day; but this difference is not nearly so great in winter as in summer. Indeed during that season of the year the quantity is often as great or even greater during the day than during the night.[3]

The reason why the quantity of carbonic acid gas in the atmosphere is greater in the superior strata than at the surface of the earth, is, probably, that vegetables have the property of absorbing it and applying it to the purposes of vegetation. Hence, doubtless, the reason why it does not increase, notwithstanding the prodigious quantity of it constantly thrown into the atmosphere by the breathing of animals and the combustion of fuel.

Atmosphere. Its quantity.

If we admit the mean volume of carbonic acid gas in air to be 0·000415, then the true component parts of 100 volumes of air will be

Azotic gas	79·9668
Oxygen gas	19·9917
Carbonic acid gas	0·0415
	100.

This, doubtless, will somewhat modify the specific gravity of oxygen and azotic gases; but the alteration is too insignificant to claim any attention.

Air contains vapour.

Besides these three constituents, there is a fourth, namely, the vapour of water, from which air is never altogether free, and the proportion of which, owing to causes which cannot at present be fully explained, is continually altering. The consequence of this is, that if we weigh air in its natural state ever so often, we shall hardly ever find its weight in any two consecutive experiments altogether the same. It is sufficiently known that water evaporates spontaneously at all temperatures, and mixes with air in the state of an invisible elastic fluid known by the name of *vapour* or of *steam* when its elasticity is so great as to balance that of the atmosphere. The elasticity of vapour varies with the temperature. At 32° it is capable of supporting a column of mercury 0·2 inch high. At 80° it supports a column of 1 inch, at 163° of about 10 inches, at 180° of about 15 inches, and at 212° of about 30 inches. Now, the quantity of it which can exist in the atmosphere at the same time is proportional to this elasticity.

Its volume determined.

Mr Dalton has shown, that if p = pressure of the atmosphere in inches of mercury, f = elasticity of vapour contained in the atmosphere, x = volume of dry air in 100 volumes of the given atmospherical air; then

$$\frac{px}{p-f} = 100; \text{ consequently } x = \frac{100}{\frac{p}{p-f}}.$$

Let air be saturated with moisture at 32°. In that case we have

$$\frac{px}{p-f} = \frac{30}{29{\cdot}8} = 1{\cdot}00671$$

$$x = \frac{100}{1{\cdot}00671} = 99{\cdot}333;$$

so that the volume of vapour (supposing its specific gravity 0·625) in 100 volumes of such air will amount to 0·666, which is just $\frac{1}{150}$th part of the volume of the air.

At the temperature of 60° $f = 0{\cdot}52$, we have therefore $\frac{px}{p-f} = \frac{30\,x}{29{\cdot}48} = 100$, and $x = 98{\cdot}267$; so that the volume of vapour capable of existing in the atmosphere at 60° is $\frac{17{\cdot}33}{100{\cdot}000}$ of the atmosphere.

The highest temperature that the writer of this article has had an opportunity of witnessing in Great Britain was 93°. At that temperature $f = 1{\cdot}5$

$$\frac{px}{p-f} = \frac{30x}{28{\cdot}5} = 100, \text{ and } x = 95;$$

so that the volume of vapour capable of existing in the atmosphere at such a temperature is $\frac{5}{100}$ or $\frac{1}{20}$.

To determine the volume of vapour in the atmosphere

Atmosphere.

at any particular time, various instruments have been contrived, called *hygrometers*, some more and some less exact; but the simplest and most accurate method of all is that employed by Leroi, and afterwards by Mr Dalton. Take a glass tumbler, as thin as possible, and fill it with water somewhat colder than the temperature of the air at the time. Observe if vapour be condensed on the outside of the tumbler; if not, the water employed is not cold enough for our purpose. Its temperature must be lowered either by putting pieces of ice into it or by dissolving in it some carbonate of soda or sulphate of soda, retaining their water of crystallization, but in powder. If vapour condense on the outside of the tumbler, pour out the water into another glass and wipe the outside of the tumbler dry. When the temperature of the water has had time to be a little elevated, pour it into the tumbler again, and observe whether moisture condense on the outside of the glass. If it do, pour out the water, wipe the outside of the tumbler again, and repeat the process when the water has become a little warmer. This method of proceeding is to be persevered in till you find the temperature at which the moisture just ceases to be condensed on the glass. That temperature, by means of the following table, will enable you to determine the volume of vapour (of the specific gravity 0·625) existing in the atmosphere at the time that your observation is made.

Atmosphere.

Temperature.	Force of Vapour in Inches of Mercury.	Temperature.	Force of Vapour in Inches of Mercury.	Temperature.	Force of Vapour in Inches of Mercury.	Temperature.	Force of Vapour in Inches of Mercury.
32°	0·2000	47°	0·3264	62°	0·5560	77°	0·9175
33	0·2066	48	0·3372	63	0·5749	78	0·9487
34	0·2134	49	0·3483	64	0·5944	79	0·9809
35	0·2204	50	0·3600	65	0·6146	80	1·0120
36	0·2277	51	0·3735	66	0·6355	81	1·04
37	0·2352	52	0·3875	67	0·6571	82	1·07
38	0·2429	53	0·4020	68	0·6794	83	1·10
39	0·2509	54	0·4171	69	0·7025	84	1·14
40	0·2600	55	0·4327	70	0·7260	85	1·17
41	0·2686	56	0·4489	71	0·7507	86	1·21
42	0·2775	57	0·4657	72	0·7762	87	1·24
43	0·2866	58	0·4832	73	0·8026	88	1·28
44	0·2961	59	0·5012	74	0·8299	89	1·32
45	0·3059	60	0·5200	75	0·8581	90	1·36
46	0·3160	61	0·5377	76	0·8873		

Suppose we find that the temperature of the water when moisture ceases to be condensed on the outside of the tumbler is 40°, we look into the above table, and opposite to 40° in it, we find 0·26 inch of mercury. This denotes the force of the vapour contained in the atmosphere at the time our experiment was made. Suppose the barometer to be standing at 30 inches, then the volume of vapour in the atmosphere is $\frac{26}{3000}$, or nearly $\frac{1}{113}$ of the volume of the atmosphere.

The absolute quantity of vapour in the atmosphere is usually greatest in summer on account of the temperature being so much higher; but the moisture or dryness of the air does not depend so much upon the absolute quantity of vapour which it contains, as on its approach to saturation. Suppose the temperature of the air to be 60°, and that a tumbler filled with water of 60° condenses water on its outside. This would indicate a force of vapour equal to 0·52 inch of mercury. Now, as this is the force of vapour at 60°, it is clear that as much vapour exists in the air as is possible at that temperature. The air is saturated with moisture, evaporation cannot go on in it, and moisture will be deposited upon all bodies the least colder than the air itself. Such a state of things takes place pretty frequently in this country during winter, though rarely during summer. Hence the atmosphere is moister during winter than during summer, though the absolute quantity of vapour which it contains may be much less.

With respect to the quantity of vapour in the atmosphere we have still very few data. Mr Daniel, in his book on Meteorology, has given a table of the force of vapour in the atmosphere at London for three years. The following table gives the mean force of vapour in Glasgow during every fortnight, from May 1823 to February 1824:

Quantity of vapour in the air at Glasgow.

		Force of Vapour in Inches of Mercury.
1823. May,	1st fortnight	0·2707
	2d	0·3494
June,	1st	0·3052
	2d	0·2822
July,	1st	0·3526
	2d	0·3819
August,	1st	0·4000
	2d	0·3546
September,	1st	0.3790
	2d	0·3404
October,	1st	0·3233
	2d	0·3026
November,	1st	0·2808
	2d	0·3230
December,	1st	0·2449
	2d	0·2453
1824. January,	1st	0·2481
	2d	0·2578
February,	1st	0·2468
	2d	0·2170

The mean force of vapour in the atmosphere in Glasgow is nearly 0·3 inch, which indicates the quantity of vapour capable of existing in the atmosphere at 45°. Now the mean temperature of Glasgow is 47°·75. It is obvious from this that the atmosphere in that part of Scotland is moist.

It would be very interesting if we knew the force of

Atmosphere. vapour at all the different seasons in the torrid zone. The regularity of the weather in these climates, and the little alteration in height of the barometer, would make a set of such observations particularly valuable. They would probably throw more light on the theory of rain than has yet been done. The only set of observations which we have seen on the quantity of vapour in countries approaching the torrid zone, are the following by Dr Heinecker, in which he gives the maximum and minimum dew points at Funchal in Madeira (lat. 32½ N.), during the year 1828, which in that part of the world was remarkably dry.

	Maximum.	Minimum.	Rain in Inches.
January	65°	50°	4·08
February	56	50	1·64
March	65	48	1·68
April	63	45	3·35
May	69	51	2·14
June	70	54	0·21
July	72	61	0·10
August	73	63	0
September	75	69	1·39
October	74	56	0
November	72·5	54	2·56
December	67	50	0·52
			17·67[1]

These observations are not sufficient to give us an accurate notion of the state of the atmosphere at Funchal. The highest dew point is 75°, indicating a force of vapour amounting to 0·8581 inch, so that the vapour at that time in the atmosphere was nearly $\frac{1}{35}$th of its volume. The lowest dew point is 45°, indicating a force of vapour amounting to 0·3059 inch, so that the vapour at that time in the atmosphere was nearly $\frac{1}{100}$ of its volume. The mean dew point deduced from the maxima and minima is 61°, indicating a force of vapour of 0·5377 inch, or a quantity of vapour amounting to nearly $\frac{1}{55}$th of the volume of the atmosphere. The mean temperature of Madeira is 66°·3. Now since the mean dew point is 61°, it is obvious that the atmosphere over Madeira is much drier than at Glasgow, though the absolute quantity of vapour which it contains is much greater.

Why the different gases in air remain mixed. Thus the atmosphere is a mixture of at least four different elastic fluids, namely, azotic gas, oxygen gas, carbonic acid gas, and the vapour of water. Doubtless all other gaseous bodies and many vapours exist in it also, but in too small quantities to be discovered by the most delicate tests that we have it in our power to apply. These different elastic fluids are mixed equably together; and though there be a considerable difference in their specific gravities, that difference has no tendency to cause them to separate. The reason of this equable mixture was first pointed out by Dalton. It depends upon a principle not yet generally recognised, but of the existence of which recent observations leave little doubt. This principle is, that the particles of elastic fluids are not mutually elastic to each other. The particles of oxygen repel the particles of oxygen, the particles of azotic gas repel those of azotic gas; but a particle of oxygen does not repel a particle of azotic gas. Hence, when a gas issues from an orifice into a space filled by another gas, it rushes precisely as if it were flowing into a vacuum. But the full development of this important principle belongs to the article Pneumatics.

Salubrity of the atmosphere. A great deal has been written about the salubrity of the atmosphere in different countries. It has been supposed, and is still believed, that the average length of life in different places depends chiefly upon the state of the atmosphere. It has been generally admitted that the atmosphere is frequently a vehicle by which diseases are communicated; and the prevalence of certain epidemic diseases, as the plague and the yellow fever, in particular places, at particular seasons, has been accounted for in this way. But no satisfactory evidence has ever been adduced to satisfy us of the accuracy of these opinions. The constituents of the atmosphere, azotic and oxygen gases, never undergo any sensible change in their proportions. Carbonic acid varies somewhat, but its proportion is always so small that it cannot be considered as a source of disease. The proportion of aqueous vapour is much more variable, and there can be no doubt that it may have an effect upon individuals predisposed to certain diseases. Consumptive patients suffer much more when they breathe a very moist than when they breathe a dry atmosphere. There are few places in the habitable globe, if there be any, where the atmosphere is constantly saturated with moisture; and it cannot prove very injurious, even to consumptive patients, except when in this state. Besides, that a very dry atmosphere is not the best adapted for the continuance of health, is obvious from the sufferings to which those who inhabit the west coast of Africa are liable during the prevalence of the sirocco, a wind so excessively dry that even the wood of the floors shrinks in consequence of its action.

Nothing has been more completely ascertained than that marshy countries are subject to intermittent fevers, and that the malignancy of these intermittent fevers increases with the heat of the climate. These diseases disappear when the marshes are drained, and therefore are connected with moisture; but that they are not owing to mere moisture, is obvious from this, that they do not appear at the sea-shore or on the banks of rivers, though the moisture be as great as in marshy countries. It is the general opinion that these diseases owe their origin to certain vapours which are given out during the putrefaction of vegetable substances; but of the nature of these *miasmata* nothing is known. In the West Indies marshes are most fatal to the inhabitants just when they are almost (but not quite) dried up by the heat of the weather. It is then that the exhalations are most abundant and most deadly. It is known that smallpox, &c. may be communicated by the mixture of a particular matter with the blood. It is possible, though not very probable, that this matter may at times exist in the atmosphere in the state of vapour, or in combination with one or other of the constituents of air, most probably the aqueous vapour, and the disease may be communicated by breathing such air. It is a conceivable thing that the matter, which, like a ferment, is capable of inducing certain diseases when it enters into the blood, may exist occasionally united to the aqueous vapour in the atmosphere.

It has been ascertained, by experiments that seem conclusive, that these noxious states of the atmosphere, however they originate, may be destroyed, and the air rendered healthy, by mixing it with chlorine. This is most easily accomplished by introducing into the chamber to be so purified a quantity of chloride of lime in an open dish and pouring on it sulphuric acid. The chlorine is disengaged and speedily fills the apartment. Then the mixture is withdrawn and the room ventilated. See Climate, Meteorology, Pneumatics. (T. T.)

ATOM (α, priv., and τέμνω), a particle of matter, so minute as to admit of no division. Atoms are the *minima*

[1] Brewster's *Journal* (new series), i. 34.

Atomic Theory || Atri.

naturæ, and are conceived to be the first principles or component parts of all physical magnitude.

ATOMIC THEORY. See CHEMISTRY.

ATOMICAL PHILOSOPHY, or the doctrine of atoms, a system which, from the hypothesis that atoms are endued with gravity and motion, accounted for the origin and formation of all things. This philosophy, first broached by Leucippus, was developed by Democritus, and afterwards cultivated and improved by Epicurus, whence it is denominated the *Epicurean Philosophy*. See EPICUREAN PHILOSOPHY.

ATONEMENT. See THEOLOGY.

ATOOI, one of the larger Sandwich Islands, in the South Pacific Ocean. Towards the north-east and north-west the country is rugged and broken, but to the southward it is more level. The hills rise from the sea with a gentle acclivity, and at a little distance back are covered with wood. The produce of this island is the same with that of the rest of the cluster; but its inhabitants greatly excel their neighbours in the management of their plantations. It is nearly 30 miles in length, and contains about 10,000 inhabitants. Long. 159. 40. W. Lat. 21. 57. N.

ATRATO, a river of New Granada, in South America, which, after a course of 250 miles, falls into the Gulf of Darien. The gold and platinum mines of Choco were on some of its affluents, and its sands are still auriferous.

ATREBATII, or ATREBATES, a people of Britain, who inhabited part of Berkshire and Wiltshire, next to the Dobuni. This was one of those Belgic colonies which came out of Gaul into Britain. Their capital was Nemetocenna, or Nemetacum, now Arras. They are mentioned by Cæsar among the nations which composed the Belgic confederacy against him; and the quota of troops which they engaged to furnish on the occasion to which he refers was 15,000. Commius of Arras was a king or chieftain among the Atrebatii of Gaul in Cæsar's time; and he seems to have possessed some influence over the Atrebatii of Britain, for he was sent by Cæsar to persuade them to submission. This circumstance renders it probable that this colony of the Atrebatii had not been settled in Britain very long before that time. The Atrebatii were amongst the British tribes which submitted to Cæsar; nor do we hear of any remarkable resistance they made against the Romans at their next invasion under Claudius. It is indeed probable that, before the time of this second invasion, they had been subdued by some of the neighbouring states; perhaps by the powerful nation of the Cattivellauni; which may also be the reason why they are so little mentioned in history. Calleva Atrebatum, mentioned in the seventh, twelfth, thirteenth, and fourteenth Itinera of Antoninus, and called by Ptolemy *Calcula*, seems to have been the British capital of the Atrebatii. But our antiquaries differ respecting the situation of this ancient city; some of them placing it at Wallingford, and others at Silchester.

ATREUS, in *Ancient History*, the son of Pelops and Hippodameia, grandson to Tantalus, and the father of Agamemnon and Menelaus, is supposed to have been king of Mycenæ and Argos about 1228 years before the Christian era. He drove his brother Thyestes from court for having criminal intercourse with Ærope his wife; but, understanding that two children were the fruit of this connection, he recalled his brother, and served up their flesh to him at a banquet; at which enormity the sun, it is said, withdrew his light.—Hygin. *Fab.*; Æschyl. *Agamemnon*; Soph. *Ajax*.

ATRI, or ATRIA, the ancient *Hadria*, a town of Naples, in the province of Abruzzo Ulteriore I., situated on a steep mountain 5 miles from the Adriatic, and 18 miles south-east of Teramo. It is the see of a bishop, and has a cathedral, a parish church, several convents and hospitals, and contains about 6000 inhabitants. In its vicinity are some remarkable ancient excavations.

Atrienses || Attachment.

ATRIENSES, in *Antiquity*, a kind of servants or officers in the great families of Rome, who had the care and inspection of the atria and the things lodged therein.

ATRIUM, in *Roman Architecture*. See ARCHITECTURE.

ATRIUM, in *Ecclesiastical Antiquity*, denotes an open place or court before a church, making part of what was called the *narthex* or *ante-temple*. The atrium in the ancient churches was a large area or square plat of ground, surrounded with a portico or cloister, situated between the porch or vestibule of the church and the body of the church. Some have erroneously confounded the atrium with the porch or vestibule, from which it was distinct; others with the narthex, of which it was only a part. The atrium was the mansion of those who were not suffered to enter farther into the church; and more particularly, it was the place where the first class of penitents stood to solicit the prayers of the faithful as they went into the church.

ATROPA, a genus of plants belonging to the natural order of Solenaceæ, most of which are active poisons. *A. Belladonna* (deadly nightshade), and *A. Mandragora*, are well-known examples.

ATROPHY (α, privative, and τροφή, a nourishment), in *Medicine*, a disease in which the body does not receive the necessary nutriment from the blood, but wastes and decays incessantly.

ATROPOS, in *Heathen Mythology*, the name of the third of the Parcæ or Fates, whose business it was to cut the thread of life.

ATTACHMENT, in *English Law*, is a process from a court of record, awarded by the justices at their discretion, on a bare suggestion, or on their own knowledge; and is properly grantable in cases of contempt. It differs from arrest, in that he who arrests a man carries him to a person of higher power to be forthwith disposed of; but he that attaches keeps the party attached, and presents him in court at the day assigned, as appears by the words of the writ. Another difference is, that arrest is only upon the body of a man, whereas an attachment is often upon his goods. It is distinguished from distress in not extending to lands, as the latter does; nor does a distress touch the body, as an attachment does. Every court of record has power to fine and imprison for contempt of its authority.

The county courts in this respect are regulated by the 9th and 10th Vict. cap. 95, § 113, and the 12th and 13th Vict. cap. 101, § 2.

The following are the ordinary instances of contempts:—

1. Contempt of the Queen's writs, *e.g.*, by witnesses not attending in pursuance of their subpœna on the trial to give evidence, and being unable to show any lawful ground of excuse (such as that of dangerous illness), or by parties proceeding in an inferior court after a prohibition or a certiorari.

2. Contempt in the face of the court.

3. Contemptuous words or writings concerning the court.

4. Contempt of the rules or awards of the court, by disobedience thereto. Under this head may be introduced the mode of punishing a party for the non-performance of an award by attachment. The first instance, it appears, of granting an attachment in such a case was in the reign of Charles II., when Kelynge was chief-justice, in Sir John Humble's case. The submission must be made a rule of court and be served on the party with an oral demand of performance of the award. An affidavit of the due execution of the award by the arbitrator is necessary, and it must be shewn that the award was made within the time limited for that purpose. There is, however, another mode of proceeding where the payment of money or of costs is awarded, by rule under the 1st and 2d Vict. cap. 110,

Attachment ‖ Attainder.

§ 18, and under which execution will issue. But an attachment cannot be obtained after proceedings under this statute.

5. Abuse of the process of the court, as suing out execution where there is no judgment, or using it in a vexatious, oppressive, or unjust manner, without colour of serving any other end thereby.

6. Forgeries of writs and other deceits tending to impose on the court, by altering the teste or filling them up after being sealed.

Attachments also lie against officers of the court for abuses committed by them; against sheriffs or other officers guilty of corrupt practice in not serving a writ, receiving a bribe in order to prevent the service, making false returns, or for exceeding their power; against attorneys for injustice or for delaying suits.

Attachments are granted on a rule in the first instance to show cause, which must be personally served before it can be made absolute, except for non-payment of costs on a master's allocatur, and against a sheriff for not obeying a rule to return a writ or to bring in the body (See order 168 of *Hilary Term*, 1853). The offender is then arrested, and when committed will be compelled to answer interrogatories, exhibited against him by the party at whose instance the proceedings have been had; and the examination when taken is referred to the master, who reports thereon, and on the contempt being reported, the court gives judgment according to their discretion, in the same manner as upon a conviction for a misdemeanour at common law.

Attachment out of Chancery, is used to enforce answers and obedience to decrees and orders of that court, and is made out without order upon an affidavit of the due service of the process, &c., with whose requirements compliance is sought. A corporation, however, is proceeded against by distringas and not by attachment.

Attachment of the Forest, is the proceeding in the courts of attachments, woodmote, or forty days' courts. These courts have now fallen into absolute desuetude. They were held before the verderors of the royal forests in different parts of the kingdom once in every 40 days, for the purpose of inquiring into all offences against "vert and venison." The attachment is by the bodies of the offenders, if taken in the very act of killing venison, or stealing wood, or preparing so to do, or by fresh and immediate pursuit after the act is done; else they must be attached by their goods. These attachments were received by the verderors and enrolled, and certified under their seals to the Court of Justice seat, or sweinmote, which formed the two superior of the forest courts.

Attachment, Foreign, a local custom in some parts of England resembling the practice of arrestment in Scotland, is the attachment of money or goods found within a liberty or city, to satisfy some creditor within such liberty or city. But it cannot be obtained where a suit is pending in any of the courts at Westminster, nor can money due to an executor or administrator as such be attached, nor trust money, nor money awarded under a rule of court. By the custom of London, and several other places, a man can attach money or goods in the hands of a stranger, to satisfy himself. (R. M—M.)

ATTACOTTI, an ancient people of Britain, mentioned by Ammianus Marcellinus and St Jerome, as well as in the *Notitia Imperii*. They were allies of the Scots and Picts, and inhabited the west coast of Scotland, but their precise boundaries have not been determined.

ATTAINDER, in the *Law of England*, imports that extinction of civil rights and capacities which takes place whenever a person who has committed treason or felony receives sentence of death for his crime, and is the immediate inseparable consequence from the common law upon the sentence of death. When it is clear beyond all dispute that the criminal is no longer fit to live, he is called *attaint, attinctus*, stained or blackened, and could not, before the 6th and 7th Vict. c. 85, § 1, be a witness in any court. This attainder takes place after judgment of death, or upon such circumstances as are equivalent to judgment of death, such as judgment of outlawry on a capital crime, pronounced for absconding from justice. Attainder.

A man is attainted by *appearance*, that is, by confession when he answers guilty upon his indictment, or by verdict, when he pleads not guilty, but is found guilty by the jury; by *process*, otherwise called judgment by default or outlawry, when the party fleeth, and is not to be found in the country, and is outlawed on the fifth proclamation upon his default; and by *act of parliament*.

The consequences of attainder are—1st, Forfeiture; 2d, Corruption of blood.

1*st, Of forfeiture:*

The offender becomes incapable of maintaining a suit in any court of justice, whether civil or criminal, except for the purpose of procuring the reversal of his attainder. In cases of treason or murder, or of abetting, procuring, or counselling the same (to which, by the 54th Geo. III. cap. 145, it is limited), all lands and tenements of inheritance, whether fee-simple or fee-tail, and all rights of entry in lands or tenements at the time of the commission of the offence, or at any time afterwards, and all the profits of all lands and tenements which the offender had in his own right, for life or years, so long as such interest shall subsist, are forfeited to the crown. He also forfeits all his chattel interests absolutely, and the profits of all estates of freehold during life; and this forfeiture of goods and chattels accrues in every treason or misprision thereof, felonies of all sorts, self-murder, or felony-de-se.

There is, however, this distinction between the forfeiture of lands, and of goods and chattels: lands are not forfeited before attainder, and the forfeiture has relation back to the time of the commission of the offence, so as to avoid all intermediate sales and incumbrances; goods and chattels are forfeited by conviction, and the forfeiture has no relation backwards.

2*d, Of corruption of blood:*

The ancient law has been much narrowed in its application by recent enactments. Formerly the person attainted was incapable himself of inheriting, or of transmitting his own property by heirship; and this corruption could not be absolutely removed but by authority of parliament.

But now, under the 54th Geo. III. cap. 145, no attainder for felony, except for treason or murder, extends to the disinheriting of any person, nor to the prejudice of the right or title of any person beyond the natural life of the offender; and by the 3d and 4th Will. IV. cap. 106, § 10, when the person, from whom the descent of any land is to be traced, shall have had any relation who, having been attainted, shall have died before such descent shall have taken place, then such attainder shall not prevent any person from inheriting such land, who would have been capable of inheriting the same by tracing his descent through such relation, if he had not been attainted; and by the 13th and 14th Vict. cap. 60, § 46, no lands, stock, or chose in action, vested in any person on any trust, or by way of mortgage, or any profits thereof, shall be forfeited by reason of attainder or conviction for any offence of such trustee or mortgagee, but the Court of Chancery has power, under the 15th and 16th Vict. cap. 55, § 8, to appoint new trustees in lieu of persons convicted of felony.

It is, however, in the power of the Sovereign to restore the forfeited land by grant to the families of the former owner, and the consequences of this forfeiture are, therefore, at the present time frequently remitted.

Attainder and conviction must be taken advantage of by plea.

Attainders may be reversed or falsified (*i.e.*, proved to be false) by writ of error, or by plea. If by writ of error, it

Attalea || Atterbury.

must be by the Queen's leave, &c.; and when by plea, it must be by denying the treason, pleading a pardon by act of parliament, &c.

By a reversal of attainder, all the former proceedings are absolutely set aside, and the party stands as if he had never been accused, and is restored to his credit, his capacity and blood, and his estates,—by a free pardon the person cannot sue on any right accrued before his pardon, although he may for a subsequent right. (R. M—M.)

ATTALEA, an important genus of palms, described by Spix and Martins as found in the dense forests of Brazil. The fibres of the leaf-stalks of *A. funifera* afford the finest cordage for the Brazilian navy. The fruit of *A. compta* is about the size of the egg of a goose, and contains an esculent kernel. Its leaves form excellent thatch. *A. speciosa* affords oily nuts, which are applied to various useful purposes in Brazil.

ATTALEIA (now ADALIA), a maritime city of Pamphylia, near the mouth of the Catarrhactes, visited by Paul and Barnabas, A.D. 45. Extensive ruins attest its former greatness.

ATTAR, or OTTO of ROSES, a well-known perfume of great strength, is an essential oil prepared in several parts of Asia and in Egypt from the *Rosa moschata* and *Rosa Damascena*. It is said that 100,000 roses yield but 180 grains of attar. This oil is at first of a palish green colour, which by keeping becomes darker, and presents various tints of green, yellow, and red.

ATTENTATES, proceedings in a court of judicature, after an inhibition is decreed.

ATTENTION, a due application of the ear or of the mind to anything said or done, in order to acquire a knowledge thereof. The word is compounded of *ad*, to, and the verbal substantive derived from *tendo*, I stretch.

Attention, in respect of hearing, is the stretching or straining of the *membrana tympani*, so as to make it more susceptible of sounds, and better prepared to catch even a feeble agitation of the air; or it is the adjusting of the tension of that membrane to the degree of loudness or lowness of the sound to which we are attentive.

According to the degree of attention, objects make a stronger or weaker impression. Attention is requisite even to the simple act of seeing: the eye can take in a considerable field at one look, but no object in the field is seen distinctly except that singly which fixes the attention: in a profound reverie, which totally occupies the attention, we scarcely see what is directly before us. In a train of perceptions, no particular object makes such a figure as it would do singly and apart; for when the attention is divided among many objects, no particular object is entitled to a large share. Hence the stillness of night contributes to terror, there being nothing to divert the attention.

Attention is classed by Dugald Stewart as a distinct faculty of the mind; an arrangement from which some other philosophers have dissented. But his admirable illustrations of the effects or results of attention are not at all dependent on the opinion which may be formed on this question.—See *Elements of the Philosophy of the Human Mind*, ch. ii.

ATTENUATION (*ad* and *tenuis*), the act of making any fluid thinner and less consistent than it was before, or of enlarging bodies in superficial extent.

ATTERBURY, FRANCIS, a man who holds a conspicuous place in the political, ecclesiastical, and literary history of England, was born in the year 1662, at Middleton in Buckinghamshire, a parish of which his father was rector. Francis was educated at Westminster School, and carried thence to Christ Church a stock of learning which, though really scanty, he through life exhibited with such judicious ostentation that superficial observers believed his attainments to be immense. At Oxford, his parts, his taste, and his bold, contemptuous, and imperious spirit soon made him conspicuous. Here he published, at twenty, his first work, a translation of the noble poem of Absalom and Ahithophel into Latin verse. Neither the style nor the versification of the young scholar was that of the Augustan age. In English composition he succeeded much better. In 1687 he distinguished himself among many able men who wrote in defence of the Church of England, then persecuted by James II., and calumniated by apostates who had for lucre quitted her communion. Among these apostates none was more active or malignant than Obadiah Walker, who was master of University College, and who had set up there, under the royal patronage, a press for printing tracts against the established religion. In one of these tracts, written apparently by Walker himself, many aspersions were thrown on Martin Luther. Atterbury undertook to defend the great Saxon reformer, and performed that task in a manner singularly characteristic. Whoever examines his reply to Walker will be struck by the contrast between the feebleness of those parts which are argumentative and defensive, and the vigour of those parts which are rhetorical and aggressive. The Papists were so much galled by the sarcasms and invectives of the young polemic, that they raised a cry of treason, and accused him of having, by implication, called King James a Judas. Atterbury.

After the Revolution, Atterbury, though bred in the doctrines of non-resistance and passive obedience, readily swore fealty to the new government. In no long time he took holy orders. He occasionally preached in London with an eloquence which raised his reputation, and soon had the honour of being appointed one of the royal chaplains. But he ordinarily resided at Oxford, where he took an active part in academical business, directed the classical studies of the under-graduates of his college, and was the chief adviser and assistant of Dean Aldrich, a divine now chiefly remembered by his catches, but renowned among his contemporaries as a scholar, a Tory, and a high-churchman. It was the practice, not a very judicious practice, of Aldrich, to employ the most promising youths of his college in editing Greek and Latin books. Among the studious and well-disposed lads who were, unfortunately for themselves, induced to become teachers of philology when they should have been content to be learners, was Charles Boyle, son of the Earl of Orrery, and nephew of Robert Boyle, the great experimental philosopher. The task assigned to Charles Boyle was to prepare a new edition of one of the most worthless books in existence. It was a fashion among those Greeks and Romans who cultivated rhetoric as an art, to compose epistles and harangues in the names of eminent men. Some of these counterfeits are fabricated with such exquisite taste and skill, that it is the highest achievement of criticism to distinguish them from originals. Others are so feebly and rudely executed that they can hardly impose on an intelligent schoolboy. The best specimen which has come down to us is perhaps the oration for Marcellus, such an imitation of Tully's eloquence as Tully would himself have read with wonder and delight. The worst specimen is perhaps a collection of letters purporting to have been written by that Phalaris who governed Agrigentum more than 500 years before the Christian era. The evidence, both internal and external, against the genuineness of these letters is overwhelming. When, in the fifteenth century, they emerged, in company with much that was far more valuable, from their obscurity, they were pronounced spurious by Politian, the greatest scholar of Italy, and by Erasmus, the greatest scholar on our side of the Alps. In truth, it would be as easy to persuade an educated Englishman, that one of Johnson's Ramblers was the work of William Wallace, as to persuade a man like Erasmus, that a pedantic exercise, composed in the trim and artificial Attic of the time of Julian, was a despatch written by a crafty and ferocious Dorian who roasted people alive many

Atterbury. years before there existed a volume of prose in the Greek language. But though Christ Church could boast of many good Latinists, of many good English writers, and of a greater number of clever and fashionable men of the world than belonged to any other academic body, there was not then in the college a single man capable of distinguishing between the infancy and the dotage of Greek literature. So superficial indeed was the learning of the rulers of this celebrated society, that they were charmed by an essay which Sir William Temple published in praise of the ancient writers. It now seems strange, that even the eminent public services, the deserved popularity, and the graceful style of Temple, should have saved so silly a performance from universal contempt. Of the books which he most vehemently eulogized his eulogies proved that he knew nothing. In fact, he could not read a line of the language in which they were written. Among many other foolish things, he said that the letters of Phalaris were the oldest letters and also the best in the world. Whatever Temple wrote attracted notice. People who had never heard of the Epistles of Phalaris began to inquire about them. Aldrich, who knew very little Greek, took the word of Temple who knew none, and desired Boyle to prepare a new edition of these admirable compositions which, having long slept in obscurity, had become on a sudden objects of general interest.

The edition was prepared with the help of Atterbury, who was Boyle's tutor, and of some other members of the college. It was an edition such as might be expected from people who would stoop to edite such a book. The notes were worthy of the text; the Latin version worthy of the Greek original. The volume would have been forgotten in a month, had not a misunderstanding about a manuscript arisen between the young editor and the greatest scholar that had appeared in Europe since the revival of letters, Richard Bentley. The manuscript was in Bentley's keeping. Boyle wished it to be collated. A mischief-making bookseller informed him that Bentley had refused to lend it, which was false, and also that Bentley had spoken contemptuously of the letters attributed to Phalaris, and of the critics who were taken in by such counterfeits, which was perfectly true. Boyle, much provoked, paid, in his preface, a bitterly ironical compliment to Bentley's courtesy. Bentley revenged himself by a short dissertation, in which he proved that the epistles were spurious, and the new edition of them worthless: but he treated Boyle personally with civility as a young gentleman of great hopes, whose love of learning was highly commendable, and who deserved to have had better instructors.

Few things in literary history are more extraordinary than the storm which this little dissertation raised. Bentley had treated Boyle with forbearance; but he had treated Christ Church with contempt; and the Christ-Churchmen, wherever dispersed, were as much attached to their college as a Scotchman to his country, or a Jesuit to his order. Their influence was great. They were dominant at Oxford, powerful in the Inns of Court and in the College of Physicians, conspicuous in parliament and in the literary and fashionable circles of London. Their unanimous cry was, that the honour of the college must be vindicated, that the insolent Cambridge pedant must be put down. Poor Boyle was unequal to the task, and disinclined to it. It was, therefore, assigned to his tutor Atterbury.

The answer to Bentley, which bears the name of Boyle, but which was, in truth, no more the work of Boyle than the letters to which the controversy related were the work of Phalaris, is now read only by the curious, and will in all probability never be reprinted again. But it had its day of noisy popularity. It was to be found not only in the studies of men of letters, but on the tables of the most brilliant drawing-rooms of Soho Square and Covent Garden. Even the beaus and coquettes of that age, the Wildairs and the Lady Lurewells, the Mirabels, and the Millamants, congratulated each other on the way in which the gay young gentleman, whose erudition sate so easily upon him, and who wrote with so much pleasantry and good breeding about the Attic dialect and the anapæstic measure, Sicilian talents and Thericlean cups, had bantered the queer prig of a doctor. Nor was the applause of the multitude undeserved. The book is, indeed, Atterbury's masterpiece, and gives a higher notion of his powers than any of those works to which he put his name. That he was altogether in the wrong on the main question, and on all the collateral questions springing out of it, that his knowledge of the language, the literature, and the history of Greece, was not equal to what many freshmen now bring up every year to Cambridge and Oxford, and that some of his blunders seem rather to deserve a flogging than a refutation, is true; and therefore it is that his performance is, in the highest degree, interesting and valuable to a judicious reader. It is good by reason of its exceeding badness. It is the most extraordinary instance that exists of the art of making much show with little substance. There is no difficulty, says the steward of Moliere's miser, in giving a fine dinner with plenty of money: the really great cook is he who can set out a banquet with no money at all. That Bentley should have written excellently on ancient chronology and geography, on the development of the Greek language, and the origin of the Greek drama, is not strange. But that Atterbury should, during some years, have been thought to have treated these subjects much better than Bentley, is strange indeed. It is true that the champion of Christ Church had all the help which the most celebrated members of that society could give him. Smalridge contributed some very good wit; Friend and others some very bad archæology and philology. But the greater part of the volume was entirely Atterbury's: what was not his own was revised and retouched by him; and the whole bears the mark of his mind, a mind inexhaustibly rich in all the resources of controversy, and familiar with all the artifices which make falsehood look like truth, and ignorance like knowledge. He had little gold; but he beat that little out to the very thinnest leaf, and spread it over so vast a surface, that to those who judged by a glance, and who did not resort to balances and tests, the glittering heap of worthless matter which he produced seemed to be an inestimable treasure of massy bullion. Such arguments as he had he placed in the clearest light. Where he had no arguments, he resorted to personalities, sometimes serious, generally ludicrous, always clever and cutting. But, whether he was grave or merry, whether he reasoned or sneered, his style was always pure, polished, and easy.

Atterbury.

Party-spirit then ran high; yet, though Bentley ranked among Whigs, and Christ Church was a stronghold of Toryism, Whigs joined with Tories in applauding Atterbury's volume. Garth insulted Bentley, and extolled Boyle in lines which are now never quoted except to be laughed at. Swift, in his Battle of the Books, introduced with much pleasantry Boyle, clad in armour, the gift of all the gods, and directed by Apollo in the form of a human friend, for whose name a blank is left which may easily be filled up. The youth, so accoutred and so assisted, gains an easy victory over his uncourteous and boastful antagonist. Bentley, meanwhile, was supported by the consciousness of an immeasurable superiority, and encouraged by the voices of the few who were really competent to judge the combat. "No man," he said, justly and nobly, "was ever written down but by himself." He spent two years in preparing a reply, which will never cease to be read and prized while the literature of ancient Greece is studied in any part of the world. This reply proved not only that the letters ascribed to Phalaris were spurious, but that Atterbury, with all his wit, his eloquence, his skill in controversial fence, was the most audacious pretender that ever wrote about what he did not understand. But to Atterbury this exposure was matter of

Atterbury. indifference. He was now engaged in a dispute about matters far more important and exciting than the laws of Zaleucus and the laws of Charondas. The rage of religious factions was extreme. High church and low church divided the nation. The great majority of the clergy were on the high church side; the majority of King William's bishops were inclined to latitudinarianism. A dispute arose between the two parties touching the extent of the powers of the Lower House of Convocation. Atterbury thrust himself eagerly into the front rank of the high-churchmen. Those who take a comprehensive and impartial view of his whole career, will not be disposed to give him credit for religious zeal. But it was his nature to be vehement and pugnacious in the cause of every fraternity of which he was a member. He had defended the genuineness of a spurious book simply because Christ Church had put forth an edition of that book; he now stood up for the clergy against the civil power simply because he was a clergyman, and for the priests against the episcopal order, simply because he was as yet only a priest. He asserted the pretensions of the class to which he belonged in several treatises written with much wit, ingenuity, audacity, and acrimony. In this, as in his first controversy, he was opposed to antagonists whose knowledge of the subject in dispute was far superior to his; but in this, as in his first controversy, he imposed on the multitude by bold assertion, by sarcasm, by declamation, and, above all, by his peculiar knack of exhibiting a little erudition in such a manner as to make it look like a great deal. Having passed himself off on the world as a greater master of classical learning than Bentley, he now passed himself off as a greater master of ecclesiastical learning than Wake or Gibson. By the great body of the clergy he was regarded as the ablest and most intrepid tribune that had ever defended their rights against the oligarchy of prelates. The Lower House of Convocation voted him thanks for his services; the University of Oxford created him a doctor of divinity; and soon after the accession of Anne, while the Tories still had the chief weight in the government, he was promoted to the deanery of Carlisle.

Soon after he had obtained this preferment, the Whig party rose to ascendancy in the state. From that party he could expect no favour. Six years elapsed before a change of fortune took place. At length, in the year 1710, the prosecution of Sacheverell produced a formidable explosion of high-church fanaticism. At such a moment Atterbury could not fail to be conspicuous. His inordinate zeal for the body to which he belonged, his turbulent and aspiring temper, his rare talents for agitation and for controversy were again signally displayed. He bore a chief part in framing that artful and eloquent speech which the accused divine pronounced at the bar of the Lords, and which presents a singular contrast to the absurd and scurrilous sermon which had very unwisely been honoured with impeachment. During the troubled and anxious months which followed the trial, Atterbury was among the most active of those pamphleteers who inflamed the nation against the Whig ministry and the Whig parliament. When the ministry had been changed and the parliament dissolved, rewards were showered upon him. The Lower House of Convocation elected him prolocutor. The Queen appointed him Dean of Christ Church on the death of his old friend and patron Aldrich. The college would have preferred a gentler ruler. Nevertheless, the new head was received with every mark of honour. A congratulatory oration in Latin was addressed to him in the magnificent vestibule of the hall; and he in reply professed the warmest attachment to the venerable house in which he had been educated, and paid many gracious compliments to those over whom he was to preside. But it was not in his nature to be a mild or an equitable governor. He had left the chapter of Carlisle distracted by quarrels. He found Christ Church at peace; but in three months his despotic and contentious temper did at Christ Church what it had done at Carlisle. He was succeeded in both his deaneries by the humane and accomplished Smalridge, who gently complained of the state in which both had been left. "Atterbury goes before, and sets everything on fire. I come after him with a bucket of water." It was said by Atterbury's enemies that he was made a bishop because he was so bad a dean. Under his administration Christ Church was in confusion, scandalous altercations took place, opprobrious words were exchanged; and there was reason to fear that the great Tory college would be ruined by the tyranny of the great Tory doctor. He was soon removed to the bishopric of Rochester, which was then always united with the deanery of Westminster. Still higher dignities seemed to be before him. For, though there were many able men on the episcopal bench, there was none who equalled or approached him in parliamentary talents. Had his party continued in power, it is not improbable that he would have been raised to the archbishopric of Canterbury. The more splendid his prospects, the more reason he had to dread the accession of a family which was well known to be partial to the Whigs. There is every reason to believe that he was one of those politicians who hoped that they might be able, during the life of Anne, to prepare matters in such a way that at her decease there might be little difficulty in setting aside the Act of Settlement and placing the Pretender on the throne. Her sudden death confounded the projects of these conspirators. Atterbury, who wanted no kind of courage, implored his confederates to proclaim James III., and offered to accompany the heralds in lawn sleeves. But he found even the bravest soldiers of his party irresolute, and exclaimed, not, it is said, without interjections which ill became the mouth of a father of the church, that the best of all causes and the most precious of all moments had been pusillanimously thrown away. He acquiesced in what he could not prevent, took the oaths to the House of Hanover, and at the coronation officiated with the outward show of zeal, and did his best to ingratiate himself with the royal family. But his servility was requited with cold contempt. No creature is so revengeful as a proud man who has humbled himself in vain. Atterbury became the most factious and pertinacious of all the opponents of the government. In the House of Lords his oratory, lucid, pointed, lively, and set off with every grace of pronunciation and of gesture, extorted the attention and admiration even of a hostile majority. Some of the most remarkable protests which appear in the journals of the peers were drawn up by him; and, in some of the bitterest of those pamphlets which called on the English to stand up for their country against the aliens who had come from beyond the seas to oppress and plunder her, critics easily detected his style. When the rebellion of 1715 broke out, he refused to sign the paper in which the bishops of the province of Canterbury declared their attachment to the Protestant succession. He busied himself in electioneering, especially at Westminster, where as dean he possessed great influence; and was, indeed, strongly suspected of having once set on a riotous mob to prevent his Whig fellow-citizens from polling.

Atterbury

After having been long in indirect communication with the exiled family, he, in 1717, began to correspond directly with the Pretender. The first letter of the correspondence is extant. In that letter Atterbury boasts of having, during many years past, neglected no opportunity of serving the Jacobite cause. "My daily prayer," he says, "is that you may have success. May I live to see that day, and live no longer than I do what is in my power to forward it." It is to be remembered that he who wrote thus was a man bound to set to the church of which he was overseer an example of strict probity; that he had repeatedly sworn allegiance to the House of Brunswick; that he had assisted in placing

Atterbury. the crown on the head of George I., and that he had abjured James III., "without equivocation or mental reservation, on the true faith of a Christian."

It is agreeable to turn from his public to his private life. His turbulent spirit, wearied with faction and treason, now and then required repose, and found it in domestic endearments, and in the society of the most illustrious of the living and of the dead. Of his wife little is known: but between him and his daughter there was an affection singularly close and tender. The gentleness of his manners when he was in the company of a few friends was such as seemed hardly credible to those who knew him only by his writings and speeches. The charm of his "softer hour" has been commemorated by one of those friends in imperishable verse. Though Atterbury's classical attainments were not great, his taste in English literature was excellent; and his admiration of genius was so strong that it overpowered even his political and religious antipathies. His fondness for Milton, the mortal enemy of the Stuarts and of the church, was such as to many Tories seemed a crime. On the sad night on which Addison was laid in the chapel of Henry VII., the Westminster boys remarked that Atterbury read the funeral service with a peculiar tenderness and solemnity. The favourite companions, however, of the great Tory prelate were, as might have been expected, men whose politics had at least a tinge of Toryism. He lived on friendly terms with Swift, Arbuthnot, and Gay. With Prior he had a close intimacy, which some misunderstanding about public affairs at last dissolved. Pope found in Atterbury not only a warm admirer, but a most faithful, fearless, and judicious adviser. The poet was a frequent guest at the episcopal palace among the elms of Bromley, and entertained not the slightest suspicion that his host, now declining in years, confined to an easy chair by gout, and apparently devoted to literature, was deeply concerned in criminal and perilous designs against the government.

The spirit of the Jacobites had been cowed by the events of 1715. It revived in 1721. The failure of the South Sea project, the panic in the money market, the downfall of great commercial houses, the distress from which no part of the kingdom was exempt, had produced general discontent. It seemed not improbable that at such a moment an insurrection might be successful. An insurrection was planned. The streets of London were to be barricaded; the Tower and the Bank were to be surprised; King George, his family, and his chief captains and councillors were to be arrested, and King James was to be proclaimed. The design became known to the Duke of Orleans, regent of France, who was on terms of friendship with the House of Hanover. He put the English government on its guard. Some of the chief malcontents were committed to prison; and among them was Atterbury. No bishop of the Church of England had been taken into custody since that memorable day when the applauses and prayers of all London had followed the seven bishops to the gate of the Tower. The Opposition entertained some hope that it might be possible to excite among the people an enthusiasm resembling that of their fathers, who rushed into the waters of the Thames to implore the blessing of Sancroft. Pictures of the heroic confessor in his cell were exhibited at the shop windows. Verses in his praise were sung about the streets. The restraints by which he was prevented from communicating with his accomplices were represented as cruelties worthy of the dungeons of the Inquisition. Strong appeals were made to the priesthood. Would they tamely permit so gross an insult to be offered to their cloth? Would they suffer the ablest, the most eloquent member of their profession, the man who had so often stood up for their rights against the civil power, to be treated like the vilest of mankind? There was considerable excitement; but it was allayed by a temperate and artful letter to the clergy, the work, in all probability, of Bishop Gibson, who stood high in the favour of Walpole, and shortly after Atterbury became minister for ecclesiastical affairs.

Atterbury remained in close confinement during some months. He had carried on his correspondence with the exiled family so cautiously that the circumstantial proofs of his guilt, though sufficient to produce entire moral conviction, were not sufficient to justify legal conviction. He could be reached only by a bill of pains and penalties. Such a bill the Whig party, then decidedly predominant in both houses, was quite prepared to support. Many hotheaded members of that party were eager to follow the precedent which had been set in the case of Sir John Fenwick, and to pass an act for cutting off the bishop's head. Cadogan, who commanded the army, a brave soldier, but a headstrong politician, is said to have exclaimed with great vehemence: "Fling him to the lions in the Tower." But the wiser and more humane Walpole was always unwilling to shed blood; and his influence prevailed. When parliament met, the evidence against the bishop was laid before committees of both houses. Those committees reported that his guilt was proved. In the Commons a resolution, pronouncing him a traitor, was carried by nearly two to one. A bill was then introduced which provided that he should be deprived of his spiritual dignities, that he should be banished for life, and that no British subject should hold any intercourse with him except by the royal permission.

This bill passed the Commons with little difficulty. For the bishop, though invited to defend himself, chose to reserve his defence for the assembly of which he was a member. In the Lords the contest was sharp. The young Duke of Wharton, distinguished by his parts, his dissoluteness, and his versatility, spoke for Atterbury with great effect; and Atterbury's own voice was heard for the last time by that unfriendly audience which had so often listened to him with mingled aversion and delight. He produced few witnesses, nor did those witnesses say much that could be of service to him. Among them was Pope. He was called to prove that, while he was an inmate of the palace at Bromley, the bishop's time was completely occupied by literary and domestic matters, and that no leisure was left for plotting. But Pope, who was quite unaccustomed to speak in public, lost his head, and, as he afterwards owned, though he had only ten words to say, made two or three blunders.

The bill finally passed the Lords by eighty-three votes to forty-three. The bishops, with a single exception, were in the majority. Their conduct drew on them a sharp taunt from Lord Bathurst, a warm friend of Atterbury and a zealous Tory. "The wild Indians," he said, "give no quarter, because they believe that they shall inherit the skill and prowess of every adversary whom they destroy. Perhaps the animosity of the right reverend prelates to their brother may be explained in the same way."

Atterbury took leave of those whom he loved with a dignity and tenderness worthy of a better man. Three fine lines of his favourite poet were often in his mouth:—

> "Some natural tears he dropped, but wiped them soon:
> The world was all before him, where to chuse
> His place of rest, and providence his guide."

At parting he presented Pope with a Bible, and said with a disingenuousness of which no man who had studied the Bible to much purpose would have been guilty: "If ever you learn that I have any dealings with the Pretender, I give you leave to say that my punishment is just." Pope at this time really believed the bishop to be an injured man. Arbuthnot seems to have been of the same opinion. Swift, a few months later, ridiculed with great bitterness, in the Voyage to Lapute, the evidence which had satisfied the two houses of parliament. Soon, however, the most partial friends of the banished prelate ceased to assert his innocence, and contented themselves with lamenting and excusing what they could not defend. After a short stay at Brussels, he had

Atterbury ‖ Attica.

taken up his abode at Paris, and had become the leading man among the Jacobite refugees who were assembled there. He was invited to Rome by the Pretender, who then held his mock court under the immediate protection of the Pope. But Atterbury felt that a bishop of the Church of England would be strangely out of place at the Vatican, and declined the invitation. During some months, however, he might flatter himself that he stood high in the good graces of James. The correspondence between the master and the servant was constant, Atterbury's merits were warmly acknowledged, his advice was respectfully received, and he was, as Bolingbroke had been before him, the prime minister of a king without a kingdom. But the new favourite found, as Bolingbroke had found before him, that it was quite as hard to keep the shadow of power under a vagrant and mendicant prince as to keep the reality of power at Westminster. Though James had neither territories nor revenues, neither army nor navy, there was more faction and more intrigue among his courtiers than among those of his successful rival. Atterbury soon perceived that his counsels were disregarded, if not distrusted. His proud spirit was deeply wounded. He quitted Paris, fixed his residence at Montpelier, gave up politics, and devoted himself entirely to letters. In the sixth year of his exile he had so severe an illness that his daughter, herself in very delicate health, determined to run all risks that she might see him once more. Having obtained a license from the English Government, she went by sea to Bordeaux, but landed there in such a state that she could travel only by boat or in a litter. Her father, in spite of his infirmities, set out from Montpelier to meet her; and she, with the impatience which is often the sign of approaching death, hastened towards him. Those who were about her in vain implored her to travel slowly. She said that every hour was precious, that she only wished to see her papa and to die. She met him at Toulouse, embraced him, received from his hand the sacred bread and wine, and thanked God that they had passed one day in each other's society before they parted for ever. She died that night.

It was some time before even the strong mind of Atterbury recovered from this cruel blow. As soon as he was himself again he became eager for action and conflict: for grief, which disposes gentle natures to retirement, to inaction, and to meditation, only makes restless spirits more restless. The Pretender, dull and bigoted as he was, had found out that he had not acted wisely in parting with one who, though a heretic, was, in abilities and accomplishments, the foremost man of the Jacobite party. The bishop was courted back, and was without much difficulty induced to return to Paris and to become once more the phantom minister of a phantom monarchy. But his long and troubled life was drawing to a close. To the last, however, his intellect retained all its keenness and vigour. He learned, in the ninth year of his banishment, that he had been accused by Oldmixon, as dishonest and malignant a scribbler as any that has been saved from oblivion by the Dunciad, of having, in concert with other Christ Churchmen, garbled Clarendon's History of the Rebellion. The charge, as respected Atterbury, had not the slightest foundation: for he was not one of the editors of the History, and never saw it till it was printed. He published a short vindication of himself, which is a model in its kind, luminous, temperate, and dignified. A copy of this little work he sent to the Pretender, with a letter singularly eloquent and graceful. It was impossible, the old man said, that he should write anything on such a subject without being reminded of the resemblance between his own fate and that of Clarendon. They were the only two English subjects that had ever been banished from their country and debarred from all communication with their friends by act of parliament. But here the resemblance ended. One of the exiles had been so happy to bear a chief part in the restoration of the Royal house. All that the other could now do was to die asserting the rights of that house to the last. A few weeks after this letter was written Atterbury died. He had just completed his seventieth year.

Atterbury ‖ Attica.

His body was brought to England, and laid, with great privacy, under the nave of Westminster Abbey. Only three mourners followed the coffin. No inscription marks the grave. That the epitaph with which Pope honoured the memory of his friend does not appear on the walls of the great national cemetery is no subject of regret: for nothing worse was ever written by Colley Cibber.

Those who wish for more complete information about Atterbury may easily collect it from his sermons and his controversial writings, from the report of the parliamentary proceedings against him, which will be found in the State Trials; from the five volumes of his correspondence, edited by Mr Nichols, and from the first volume of the Stuart papers, edited by Mr Glover. A very indulgent but a very interesting account of the Bishop's political career will be found in Lord Mahon's valuable History of England. (T. B. M.)

A T T I C A,

Boundaries and extent.

An ancient kingdom of Greece, situated between the Strait of Euripus or Negropont on the north-east, and the Gulf of Saron or Ægina on the south-west. It may be considered as forming a triangle, the base of which constituted the conterminous boundery with Bœotia, while the two other sides, washed by the sea, had their vertex at the promontory of Sunium or Cape Colonna. The prolongation of the south-western side northward till it reached the extremity of the base at the foot of Mount Cithæron served as the line of demarcation between the Athenian territory and that belonging to the small state of Megara. Hence Attica may be described generally as bounded on the north-east by the channel of Negropont; on the south-west by the Gulf of Ægina and part of Megara; and on the north-west by the territory which formed the ancient Bœotia; including, within these limits an area or superficies of about 750 square miles.

Soil and climate.

The soil of Attica was not so unsuited to the purposes of agriculture as has commonly been supposed. It was, indeed, stony and uneven in many places; a considerable part consisted of bare rock, on which little or nothing could be grown; but even the less fertile portion produced barley and wheat—the latter, it is true, with difficulty; and the mildness of the climate allowed all the more valuable products of the earth to ripen the earliest and go out of season the latest. Every kind of plant and animal throve notwithstanding the poverty of the soil; and the advantages which nature had denied were, in a great measure, compensated by the effects of skill and industry. It seldom happens that the richest countries are the most productive, or that the bounty of nature, where it has been profusely lavished, is improved by corresponding exertions on the part of man. Repugnant to labour where labour can be dispensed with, it is necessity alone that compels him to earn his bread with the sweat of his brow, and to torture the ungrateful soil for its scanty products. But habits of exertion being once formed, a variety of causes gradually contribute to stimulate his activity and extend his resources. He naturally aspires to improve his condition and circumstances by all the means in his power. Experience soon teaches him better modes of exerting his industry;—as society advances, the natural reward of labour and skill is increased;—and if

Attica. the public policy of the state be wisely directed to accelerate the operation of natural causes, the most striking results may be produced, and countries originally barren covered with well-cultivated fields, teeming with abundant harvests. Such seems to have been the progression of improvement in Attica; which, though one of the least fertile of the Grecian provinces, was, by the industry and skill of its inhabitants, rendered ultimately one of the most productive in proportion to its extent, and the portion of its surface which was susceptible of cultivation.

Chief cities. The chief cities in the ancient kingdom of Attica were Athens, the capital, of which a full description has been given under that head (see article ATHENS); Eleusis, situated on the gulf of the same name, at an equal distance from Megara and the Peiræus, where the greater mysteries of Demeter were quadrennially celebrated; and, lastly, Rhamnus, famous for the temple of Amphiaraus, and a statue of the goddess Nemesis, executed by Phidias.

The history of Attica, like that of nearly every state of Greece, is almost entirely mythical down to the beginning of the Olympiads—that is, down to the year B.C. 676. All that is related concerning the period previous to that era, consists partly of fictions and partly of traditions, which no doubt have a certain historical foundation, but have been so much modified and embellished by poets and late writers that it is now impossible to say what is historical and what is not. As regards chronology in particular, it is useless to attempt to fix the exact date of any event before the commencement of the Olympiads. As, however, the legends of early Attic history are frequently alluded to by poets and other authors, they cannot be altogether passed over in any account of the history of Attica.

Ogyges. Ogyges had the reputation of being the first king of Attica; and ancient chronologers even undertook to fix the date of his reign, which has been variously set down at 150 and 200 years before the arrival of Cecrops. But we have no assurance that even the name of Ogyges was known to the older Grecian authors; and if anything can be gathered from the traditions concerning this fabulous personage, reported by later writers, it is, that at some very remote period, a flood, having desolated the rich fields of Bœotia, over which he reigned, drove many of the inhabitants to establish themselves in the adjoining district of Attica, which, though hilly, rocky, and little fruitful, was yet judged preferable to a plain country, surrounded on all sides by mountainous tracts, and consequently exposed to a recurrence of the calamity by which so many of them had been overwhelmed. We may therefore safely consign this legendary monarch to that primitive obscurity in which his existence, his origin, and his achievements, are equally involved.

There was a time when it was generally believed that Attica, and Greece in general, had received the first elements of civilization from Egypt. This belief was founded upon the tradition, that about 150 years after the time of Ogyges, Cecrops came from Egypt to Attica, and not only gave his name to the land, but founded the city of Athens, on the rock which, down to the latest times, was often called the Cecropian rock, or the Cecropian city. He is said to have introduced among the savage natives of Attica a new and simple religion, and the institution of marriage, so that, in fact, the elements of civilized life were traced to this Egyptian immigrant. But his Egyptian origin, to say the least, is extremely doubtful; for the early Greek poets and historians appear to have known nothing about him; and when at a later period Cecrops began to be spoken of, he is frequently described as a native of the Attic soil (*αὐτόχθων*). After the time of Cecrops, two other Egyptian settlers, Erechtheus and Peteus, are said to have arrived in Attica. But the fact is that all these personages are utterly fictitious, and that the traditions about them belong entirely to a home-sprung Attic fable. But although we must reject these stories about Cecrops and Erechtheus as fabulous, we are not on that account obliged to reject the tradition of an Egyptian settlement in Attica. Even if we admit that at some time or another a band of Egyptians settled among the ancient inhabitants of Greece, it is not easy to conceive how they could have affected the national character of those among whom they established themselves. The Greek language, at least, bears no trace of any such influence; and the question how far the religion and the arts were derived from Egypt, is one which cannot be satisfactorily answered until the religion of both the Greeks and Egyptians shall be much better known and understood than they are at present. The resemblance between the early works of art among the Greeks and those of Egypt can prove nothing, for the rude beginnings of the arts are more or less the same among all nations.

The list of the successors of Cecrops down to Theseus is a mere compilation, in which some of the names appear to have been invented merely to fill up a gap; others are purely mythical, and not one can safely be pronounced historical.[1] In the reign of Erechtheus, the Athenians are said to have been involved in a war with the Thracian Eumolpus, who had established himself as sovereign at Eleusis. Erechtheus fell in battle, whereupon Eleusis concluded a treaty, in which it acknowledged the supremacy of Athens. Erechtheus was succeeded by a second Cecrops, who left his throne to his son Pandion. This last king was expelled from Attica, but found a place of refuge in Megara, where he married the king's daughter, and succeeded him on the throne. He there became the father of four sons, the eldest of whom, Ægeus, on his father's death, entered Attica at the head of an army, and recovered his patrimony. For a long time he remained childless, until some mysterious oracle led him to Troezen, where he became, by Æthra, the father of Theseus, the greatest hero in Athenian story. Theseus spent the first years of his life at Troezen, and then repaired to Athens to claim Ægeus for his father, who recognized him by certain tokens, and by his valour. This Theseus, whom some writers regard as the real founder of the Athenian state, is to Athens what Hercules is to Greece in general. All the deeds and exploits which are ascribed to him cannot have been accomplished by one man, but are probably representations of what was done in the course of several generations, or even centuries. But the life of Theseus may be regarded as composed of three main acts—his journey from Troezen to Athens, his victory over the Minotaur, and the political reforms which he is said to have effected in Attica. On his way to Athens from Troezen, he cleared the wild roads which were infested by monsters and savage men, who by their robberies had almost broken off all communication between Attica and Troezen. Amid the greatest difficulties he forced his way to his father. After being recognized by him, and purified from all his bloodshed, he went to Crete to deliver Athens from a disgraceful tribute of boys and maidens, who had to be sent annually to Minos, king of Crete, and were devoured by a monster called Minotaur. On his return to Athens, his father Ægeus died. Passing over a variety of other legends, we shall proceed to consider the political institutions ascribed to Theseus. Attica is said originally to have been divided into a number of small independent states, which, under Cecrops, formed a confederacy among themselves against the inroads of foreign enemies. On that occasion, Attica is reported to have been divided into twelve districts, and Athens, under the name of Cecropia, was probably at the head of this league. Besides this division into twelve districts, another is mentioned,

[1] Thirlwall, *Hist. of Greece*, vol. i. p. 148.

Attica.

according to which the whole country was divided into four tribes, which at different times had different names. The latest of these are ascribed to Ion, the reported founder of the Ionian race, who is said to have called the four tribes after his four sons, *Teleontes* (*Geleontes*, *Gedeontes*), *Hopletes*, *Ægicores*, and *Argades*. Some of these names are descriptive of occupations, while others are of uncertain import. These four tribes seem to have been so many distinct communities, separated by descent, situation, pursuits, and religion, yet still connected by affinities of blood and language, and the occasional need of mutual assistance. Their ultimate union with Athens, as their natural head and centre, is generally described as the work of Theseus, who is thus regarded as the founder of the national unity, and of the future greatness of Athens. The legend represents him as having thus for ever put an end to the discord and hostility which had until then prevented the inhabitants of Attica from considering themselves as one people. On that occasion the greater part of the nobles probably removed to Athens, which had become the seat of government, and they there occupied the same position and rank which they had formerly held in their respective districts. The union was cemented by religion, and by the institution of national solemnities which were periodically celebrated, such as the *Synœcia* and the *Panathenœa*, in honour of the tutelary divinity Athena. The city of Athens, which until then had occupied little more than the Cecropian rock, was enlarged by the formation of new habitations at the foot and around the rock.

The constitution which Theseus is said to have given to his country remained for many centuries after him rigidly aristocratical; and he is said to have promised all the nobles an equal share in the government, reserving for himself only the command in war and the administration of justice. Although the later Greeks were fond of describing Theseus as the founder of their democratic institutions, it is quite clear that his object was to institute a gradation of ranks, and a proportionate distribution of power. Accordingly, he distributed the people into three classes, the *nobles* (Εὐπατρίδαι), *husbandmen* (γεωμόροι), and *artisans* (δημιουργοί); the first of which possessed all the political power and influence, and the right of interpreting the laws, both human and divine. The king himself was only the first among his equals, and the four kings of the ancient tribes were his perpetual assessors or colleagues. The people of Athens, that is the δῆμος, had, no doubt, the right of meeting, but they do not appear to have exercised any political influence; and the first internal struggles of which we hear at Athens were not between the king and the people, but between the king and the nobles. Theseus himself is said to have been compelled by a conspiracy of the nobles to go into exile with his family, and to leave the throne to Menestheus, a descendant of the ancient kings. Theseus is said to have died in the island of Scyros.

Menestheus, Demophon, &c.

Menestheus reigned twenty-four years. He lost his life at the siege of Troy, and was succeeded by Demophon, one of the sons of Theseus by Phædra, who was likewise present at the siege, but had the good fortune to return in safety. Demophon was succeeded by his son or brother Oxyntes, who again was succeeded by his son Aphydes; and this last was murdered by a natural brother of the name of Thymœtes. But the bastard usurper discovered many base qualities unworthy of the station he had assumed, and was at last deposed by his subjects on account of the flagrant cowardice he had displayed on a critical occasion.

Melanthus, Codrus.

Thymœtes was appropriately succeeded by a foreign adventurer called Melanthus, who, after a long reign of thirty-seven years, left the kingdom to his son Codrus. The latter reigned twenty-one years, during which period the Dorians and Heracleidæ had regained all Peloponnesus, and were upon the point of invading Attica. Codrus, being informed that the oracle had promised them victory provided they did not kill the king of the Athenians, immediately came to the resolution to die for his country. Disguising himself, therefore, as a peasant, he went into the enemy's camp, and having quarrelled with some of the common soldiers, was killed in a brawl. On the morrow the Athenians, knowing what had happened, sent to demand the body of their king, at which the invaders were so terrified that they decamped without striking a blow.

Attica.

Upon the death of Codrus, a dispute among his sons concerning the succession furnished the nobles with a pretence for ridding themselves of their kings, and changing the monarchical into a republican form of government. It was highly improbable, they said, that they should ever again have so good a king as Codrus; and, to prevent their having a worse, they resolved to have none. That they might not, however, appear ungrateful to the family of Codrus, they made his son Medon their supreme magistrate, with the title of archon; an office which was afterwards rendered decennial, but nevertheless continued in the family of Codrus. But the extinction of the Medontidæ having at last left the nobles without restraint, they not only made this office annual, but at the same time created nine archons. By the latter expedient they provided against the exorbitant power of a single person, as by the former they took away all apprehension of the archons having time to establish themselves, so as to be able to change the constitution. In a word, they now attained what they had long sought after, namely, rendering the supreme magistracy accessible to all the nobles. The name of the first of these nine annual archons (ἄρχων ἐπώνυμος) was, like that of the consuls at Rome, used to mark the year in which any event happened. The second bore the title of king (ἄρχων βασιλεύς), and represented the former kings in their capacity of high priest of the nation.[1]

Aristocracy.

Archons; Draco

There has been handed down to us an enumeration of these archons for upwards of six centuries, beginning with Creon, who lived in 682 B.C., and coming down to Herodes, who lived only sixty years prior to the Christian era. The first archon of whom we hear anything really worthy of notice was Draco. He governed Athens in the year 624 B.C., when he promulgated his written laws; but although his name is very frequently mentioned in history, no connected account can be found either of the lawgiver or of his institutions. We only know generally that his laws were excessively severe, awarding the punishment of death for the smallest offences no less than for the most heinous crimes; and that, as Demades remarked of them, they seemed to have been written with blood. For this extraordinary and undiscriminating severity he gave no other reason, than that the smallest faults appeared to him to be worthy of death, and that he could find no higher punishment for the greatest. He was far advanced in years when he legislated for Athens; and he appears to have endeavoured to act as a mediator between the people and the oppressive nobles. His laws were called sanctions (θεσμοί). The Athenians, however, soon grew weary both of the sanctions and their author; upon which Draco was obliged to retire to Ægina, where he was received in the most flattering manner. But the favour of the inhabitants of this place proved more fatal to him than the hatred of the Athenians; for coming one day into the theatre, the audience, to evince their regard for the exiled legislator, are said to have thrown their cloaks upon him, and fairly stifled the old man to death with their kindness.

[1] It is remarkable, that Athenian and Roman superstition should have agreed so exactly in the extraordinary circumstance that, after the abolition of royalty among both, and while the very name of king was abhorred as a title of civil magistracy or military command, yet equally the title and the office were scrupulously retained for the administration of religious ceremonies.

Mitylenian war.

Not long after the expulsion of Draco, we find the republic engaged in a war with the Mitylenians about the city Sigeum, situated near the mouth of the river Scamander. The Athenian army was commanded by Phrynon, and that of the Mitylenians by Pittacus, one of the seven sages of Greece; but the generals, thinking the honour of their respective countries concerned, and being at the same time desirous to spare the effusion of blood, agreed to settle the dispute by single combat. They met accordingly; but the sage, trusting more to cunning than to courage, concealed behind his shield a net, wherewith he suddenly entangled his antagonist, and easily slew him. This, however, not putting an end to the war, Periander of Corinth interposed; and both parties having submitted to his arbitration, he decreed that Sigeum should belong to the Athenians.

Cylon's conspiracy.

About seven years after the Mitylenian war, 612 B.C., a conspiracy was entered into by Cylon, son-in-law of Theagenes, prince of Megara, for the purpose of seizing on the sovereignty of Athens. The people would have readily submitted to his rule to escape from the oppression of the many nobles. But having consulted the Delphic oracle as to the most proper time, and received directions to make the attempt while the citizens of Athens were engaged in celebrating the great festival of Zeus, Cylon and his associates made themselves masters of the citadel by a *coup-de-main*, at the time when the greater part of the citizens had repaired to Elis to witness the celebration of the Olympic games. But being instantly besieged by Megacles, who was at that time archon, and soon reduced to great distress from want of water, the chief conspirator and his brother contrived to effect their escape; upon which the remainder fled for safety to the temple of Athena, where they were barbarously massacred by order of Megacles, in virtue of one of those sophistical quibbles by means of which men sometimes reconcile their minds to the perpetration of the foulest and bloodiest deeds.

War with Megara.

At this period of confusion the Megarians attacked and took both Nisæa and Salamis. The former was a place of little or no importance to any, the latter one of the very greatest in every view; but so completely were the Athenians routed in every attempt to retake it, that a law was at last passed, declaring it capital for any one to propose the recovery of Salamis. About the same time the city was disturbed by reports of frightful appearances, and filled with superstitious fears, for it was believed that the crime of Megacles was the cause of all disasters. The oracle at Delphi was therefore consulted, and an answer returned that the city must be purified by certain expiatory rites. This was accordingly done under the superintendence of one Epimenides, a Cretan, who prescribed the sacrifice of white and black sheep, and also caused many temples and chapels to be erected, including one dedicated to Contumely, and another to Impudence! This man, after looking wistfully for a long time to the port of Munychia, spoke as follows to those that were near him: "How blind is man to the future! For, did the Athenians know what mischief will one day be derived to them from this place, they would eat it with their teeth." This prediction was thought to have been accomplished 270 years after, when Antipater constrained the Athenians to admit a Macedonian garrison into that place.

Solon.

About 604 years B.C., Solon, the famed Athenian legislator, began to show himself to his countrymen. He is said to have been lineally descended from Codrus, but left by his father in circumstances rather necessitous, which obliged him to apply himself to merchandise. From the first he appeared in the character of a patriot. The shameful decree, that none under pain of death should propose the recovery of Salamis, grieved him so much, that having composed an elegy such as he thought calculated to inflame the minds of the people, he ran into the market-place as if he had been insane, repeating his verses. A crowd soon collected around the pretended madman; his kinsman Peisistratus mingled with the people, and observing them moved with Solon's words, agreed to second the patriotic poet with all the eloquence he was master of; and at length they prevailed so far as to have the law rescinded, war declared against the people of Megara, and an expedition immediately fitted out for the recovery of Salamis; which was ultimately effected by a stratagem more creditable to the ingenuity than the bravery of the Athenians.

The success of this enterprise at once established the reputation of Solon; who, on his return to Athens, was greatly honoured by the people, and soon afforded them another occasion of admiring that wisdom for which they had already given him credit. The inhabitants of Cirrha, a town situated in the Bay of Corinth, having repeatedly committed acts of extortion and violence against pilgrims proceeding to Delphi, at last besieged the capital itself, with a view of making themselves masters of the treasures contained in the temple of Apollo. Advice of this intended sacrilege having been sent to the Amphictyons, Solon advised that the matter should be universally resented, and that all the states should join in punishing the Cirrhæans, and in saving the Delphic oracle. This suggestion was adopted, and a general war against Cirrha declared, B.C. 594. Cleisthenes, prince of Sicyon, commanded in chief, and the Athenian contingent was under the orders of Alcmæon. Solon accompanied the expedition as assistant or counsellor to Cleisthenes, and under his direction the war was conducted to a prosperous issue. According to Pausanias, the city was reduced by a singular stratagem, said to have been invented by Solon. He caused the river Pleistus, which flowed through Cirrha, to be turned into another channel, hoping thereby to distress the inhabitants for want of water; but finding they had many wells within the city, and were not to be reduced by that means, he caused a vast quantity of roots of hellebore to be thrown into the river, which was then suffered to return into its former bed. The inhabitants, overjoyed at the sight of running water, came in troops to drink of it; the consequence of which was, that an epidemic flux ensued, and the citizens being no longer able to defend the walls, the town was easily captured. This, as far as we know, is the only instance on record of a town taken by physic.

Athens in great confusion.

On his return to Athens after the hellebore achievement, Solon found things again in the utmost confusion. The remnant of Cylon's faction gave out that all sorts of misfortunes had befallen the republic on account of the impiety of Megacles and his followers; and this clamour was heightened by the retaking of Salamis about the same time by the Megarians. Solon interposed, and persuading those who were styled "execrable" to abide a trial, three hundred persons were chosen to judge them. The issue was, that the whole of Megacles' party who were alive were sent into perpetual exile, and the bones of such as had died were dug up and sent beyond the limits of their country. But although this decision restored tranquillity for the time, the people were still divided into three factions, contending about the proper form of government. These were called the Diacrii, Pediæi, and Parali; the first of whom, consisting of the inhabitants of the hilly country, declared for democracy; the second, dwelling in the low country, and far more opulent than the former, were in favour of an oligarchy, wishing to keep the government in their own hands; whilst the third party, who inhabited the sea-coast, were people of moderate principles, and therefore friendly to a mixed government. But besides these agitations, disturbances of a much more serious character arose, in consequence of the lamentable condition to which the people or Demos had been reduced, in consequence of the severity of the law of debt. According to Plutarch, the poor having become indebted to the rich, either tilled their grounds and paid them the sixth part of the produce, or impignorated their persons for their

Attica.

debts, so that many were made slaves at home, and not a few sold as such into foreign countries; while some were even obliged to sell their children to pay their debts, and others in despair quitted Attica altogether. The greater part, however, were for throwing off the yoke, and began to look about for a leader, openly declaring that they intended to change the form of government, to introduce a more equitable distribution of power, and to modify the law of debt.

Solon chosen archon.

In this extremity the eyes of all were turned to Solon, and some were for offering him the sovereignty at once; but, perceiving the intentions of these misjudging persons, he refused the sovereignty tendered to him, and preferring the substance to the shadow, quietly took upon himself, without any pomp or pageantry, the unqualified exercise of the supreme authority of the state, in all its branches, and wielded it with an absolutism which would have been intolerable, had it not been conferred upon him by the unanimous consent of the people. He was chosen archon (594, B.C.) without having recourse to the ballot, an anomaly of which there is no other example; and, after his election, he proved the wisdom of the choice by disappointing the interested expectations of all parties. It was a fundamental maxim with Solon, that those laws will be best observed which power and justice equally support. Hence, wherever he found the old constitution in any measure consonant to justice, he refused to make any alteration at all, and was at extraordinary pains to show the reason of such changes as were actually introduced. In a word, being a consummate judge of mankind generally, and, above all, thoroughly conversant with the character of his countrymen, he sought to rule only by showing the people that it was their interest to obey, and contented himself with giving them such institutions as they were prepared to receive, instead of forcing upon them those which might be esteemed theoretically the most perfect. Hence, to one who inquired whether he had given the Athenians the best laws in his power, he replied, "I have established the best which they could receive."

Seisachtheia.

With reference to the main cause of discontent, namely, the oppressed state of the meaner class, Solon removed it by a scheme which he called *seisachtheia*, or discharge. Ancient authors, however, are not agreed as to the precise nature of this contrivance. Some say that he cancelled all debts then in existence, and prohibited the seizure of any man's person in default of payment of a debt for the future; whilst others affirm that the poor were relieved, not by cancelling the debts, but by lowering the interest, and increasing the value of money, so that a mina, which before was equal to seventy-three drachmas only, was by him made equal to a hundred. The more probable opinion is, that the seisachtheia was a general disburdening ordinance, which relieved the debtor partly by a reduction of the rate of interest, and partly by lowering the standard of the coinage, whereby a debtor saved more than 25 per cent. in every payment. He also released the mortgaged lands from their encumbrances, and restored them to their owners. He then abolished the cruel law, by which a creditor might enslave his debtor, and restored to freedom those who were pining in bondage. These may seem measures of extreme violence; but it must be borne in mind that the whole people had conferred upon him unlimited power, on the understanding that they would acquiesce in his legislative regulations.

But in the midst of all the glory which Solon acquired by these measures, an accident occurred which for a time clouded his reputation, and almost entirely ruined his schemes. Having, it seems, consulted Conon, Clinias, and Hipponicus, three of his friends, on an oration he had prepared with a view to engage the people's consent to the seisachtheia, these worthies, thus apprized of the contemplated measure, availed themselves of their knowledge to borrow large sums of money before the law was promulgated, with the intention to take advantage of its provisions, and refuse to repay the lenders. We cannot wonder that Solon himself was at first believed to have been cognizant of the scheme, and a partner in this fraudulent adventure. But, happily for his credit, those suspicions were obliterated when it was discovered that the lawgiver was a creditor to a large extent, and likely to become a considerable loser by the operation of his own law. His friends, however, never recovered their credit, but were ever afterwards stigmatized with the opprobrious appellation of *chrciocopidæ* or *debt-sinkers*.

Attica.

Solon now set himself to the arduous task of compiling a body of laws for the people of Attica; and having at last completed his task in the best manner he could, or at least in the best manner that the character of the people would admit, he caused them to be duly ratified, and declared to be in force for a century from the date of their publication. Those which related to private actions were preserved on parallelograms of wood, with cases which reached from the ground, and turned upon a pin like a wheel, whence the appellation of *axones;* and were placed, first in the Acropolis, and afterwards in the Prytaneium, that all the subjects of the state might have access to consult them whenever they chose. Such as concerned public institutions and sacrifices were inscribed on triangular tablets of stone called *cyrbeis*. The Athenian magistrates were sworn to observe both. With regard to the axones, or *jus privatum* of Solon, our information is exceedingly imperfect; but if it be true that the decemviral constitutions at Rome were principally borrowed from this portion of his code, the fragments which remain of these celebrated laws are certainly calculated to give us no mean idea of his fitness for the task which circumstances as well as inclination had induced him to undertake. Nor will our opinion of the legislator be lowered by attending to his system of public law; concerning which more exact details have been preserved, and some account will be given when we come to speak of the Athenian government. We may, however, here remark in general, that Solon had abolished the ancient aristocratic government, in which all rights and privileges had been determined by birth, and that he substituted a timocracy, that is, a form of government in which a man's property forms the standard by which his rights and duties are determined.

Compilation of code.

After the promulgation of his code, Solon found himself obliged to leave Athens, to avoid being continually teased for explanations and emendations of his laws. He therefore pretended an inclination to merchandise, and obtained leave to withdraw himself for ten years, in the hope that during his absence his laws would grow familiar to the people. From Athens he accordingly travelled into Egypt, where he is said to have conversed with Psamenophis of Heliopolis and Sesonchis of Sais, the most learned priests of that age, from whom he learned the situation of the island Atlantis, and wrote an account of it in verse, which Plato afterwards continued. Leaving Egypt, he is reported to have visited Cyprus, where he was well received by one of the petty kings, and assisted in the foundation of a new city, the site of which he had pointed out, and which, out of gratitude to the Athenian legislator, was called Soli.

But while Solon was thus travelling in quest of wisdom, his countrymen were again divided into three factions. Lycurgus was at the head of what may be called the country party; Megacles the son of Alcmæon swayed those who lived on the sea-coast; and Peisistratus appeared as the champion of the *demos*, under the pretence of protecting them from tyranny, but in reality with the view of seizing on the sovereignty for himself. In the midst of all this confusion the legislator returned about 562 B.C. Each of the factions affected to receive him with the deepest reverence aud respect, beseeching him to resume his authority, and compose the disorders to which they themselves had given birth. But Solon declined this hollow invitation, on the ground that his age rendered him unable to speak and act

as formerly for the good of his country; he sent however for the chiefs of each party, and entreated them in the most pathetic manner not to ruin their common parent, but to prefer the public good to their own private interest; sound advice, doubtless, but entirely thrown away on those to whom it was administered.

Peisistratus.

Peisistratus, who of all the chiefs had unquestionably the least intention of following Solon's advice, appeared to be the most affected with his discourses; but perceiving that he affected popularity by all possible methods, Solon easily penetrated into his design of assuming the sovereign power. This he spoke of privately to Peisistratus himself; but as he saw that his admonitions had no effect, he unveiled the designs of this ambitious chief, that the public might be on their guard against him and his artful machinations. But all the wise discourses of Solon were lost upon the Athenians. Peisistratus had got the lower class entirely at his devotion, and therefore resolved to cheat them out of the liberty which they were incapable of appreciating. With this view he wounded himself, then drove into the market-place, and there showed his bleeding body, imploring the protection of the people against those whom his kindness to them had rendered his implacable enemies. It was for being their declared friend, he said, that he had thus suffered. They saw it was no longer safe for a man to be a friend to the people; they saw it was no longer safe for a man to live in Attica, unless they would take him under that protection which he implored. A crowd being instantly collected, Solon came amongst the rest, and, suspecting the deceit, openly taxed Peisistratus with his perfidious conduct; but to no purpose. A general assembly of the people was summoned, wherein it was moved that Peisistratus should have a guard. Solon alone had resolution enough to oppose this measure; the richer Athenians remaining silent through fear of the multitude, which implicitly followed Peisistratus, and applauded everything he said. A guard of 400 men was then unanimously decreed to Peisistratus; and with this inconsiderable body he managed, partly by stratagem and partly by force, to possess himself of the supreme power B.C. 560. Solon inveighed bitterly against the meanness of his countrymen, in thus tamely surrendering their liberties, and attempted to rouse them to take up arms in defence of the constitution and the laws; but finding his efforts unavailing, he withdrew, remarking that he had done his utmost for his country. He submitted to the tyranny of Peisistratus merely because he had no choice between a tyranny and anarchy.

Governs with great moderation.

Peisistratus, having thus obtained the sovereignty, did not overturn the laws of Solon, but on the contrary used his power with the greatest moderation, and even courted the friendship and asked the advice of Solon. It was not in the nature of things, however, that the Athenians could long remain satisfied with this form of government. On the usurpation of Peisistratus, Megacles and his family had retired from Athens, ostensibly in order to save their own lives; but having entered into a treaty with Lycurgus, whom they brought, along with his party, into a scheme for deposing the usurper, they concerted matters so skilfully, that Peisistratus was soon after obliged to withdraw from the city; and, on his departure, the Athenians ordered his goods to be confiscated. But Megacles had no sooner succeeded in his project against Peisistratus, than, finding his ally Lycurgus intractible, he changed sides, and began to plot the return of the very man whom he had just succeeded in expelling as a tyrant and usurper. This counter project was at length effected by means of a trick worthy of the parties engaged in this little political drama. Having found out a woman of the name of Phya, of a mean family and fortune, but of great stature and very handsome person, they dressed her in armour, placed her in a chariot, and having disposed things so as to make her appear to the utmost advantage, they conducted her towards the city, sending heralds before, with orders to address the people in the following terms: "Give a kind reception, O Athenians, to Peisistratus, who is so much honoured above all other men by Athena that she herself condescends to bring him back to the citadel." The report being universally spread that Athena was bringing back Peisistratus, and the ignorant multitude believing this woman to be the goddess, addressed their prayers to her, and received Peisistratus with the utmost joy. When he had recovered the sovereignty, Peisistratus married the daughter of Megacles, in fulfilment of a stipulation made between them to that effect, and also gave the mock goddess as a wife to his son Hipparchus. This last statement renders the whole story, which in itself is extremely childish, altogether improbable.

Second expulsion.

Peisistratus did not long enjoy the authority to which he had been thus restored. He had indeed married the daughter of Megacles according to treaty; but having children by a former marriage, and remembering that the whole family of Megacles were execrated by the Athenians, he thought it expedient to suffer his new spouse to remain in a state of perpetual widowhood. This the lady bore patiently for some time; but at last acquainting her mother with the state in which she was compelled to live, the affront was highly resented; and Megacles immediately entered into a treaty with the malcontents. Peisistratus, apprised of this step on the part of his father-in-law, and perceiving that a new storm was gathering, voluntarily quitted Athens and retired to Eretria; where, having consulted with his sons, he resolved to reduce Athens, and repossess himself of power by force of arms. With this view he applied to several of the Greek states, including that of Thebes, which furnished him with the troops he desired; and at the head of a considerable force he returned to Attica,—reduced Marathon, the inhabitants of which had taken no measures for their defence,—surprised and routed the republican forces, which had marched out of Athens to attack him,—and finally, after an absence of about ten years, re-established himself in power, by using victory with his accustomed moderation.

Return.

Peisistratus being thus reinstated once more in the sovereignty, took a method of securing himself in power directly opposite to that which Theseus had adopted. For, instead of collecting the inhabitants from the country into towns, as his predecessor had done, Peisistratus, made them retire from the towns into the country, in order to apply themselves to agriculture; and thus prevented their meeting together in bodies and caballing against him as they had hitherto been accustomed to do. By this means also the territory of Athens was greatly ameliorated, and extensive plantations of olives were reared over all Attica, which had hitherto been not only destitute of corn, but also naked and bleak in appearance from the total want of trees. And had he stopped here it would have been well. But actuated by that partiality for sumptuary laws which seems to have been the foible of nearly all the ancient legislators, he commanded his subjects in the city to wear a kind of sheepskin frock reaching to the knees, and appears to have set great store by this absurd enactment, which was doubtless intended to restore the simplicity of ancient manners. The Athenians, however, vehemently resented this interference with their *habits;* and so odious did the sheepskin garment become, that in succeeding times the frock or jacket of Peisistratus was a sort of by-word for the badge or garb of slavery. Experience shows that it is comparatively an easy matter to rob men of their liberty, and trample both on their political and civil rights; but an interference with their private habits or the adornment of their persons is almost always dangerous. As prince of Athens, Peisistratus exacted for the service of the state the tenth part of every man's revenue, and even of the fruits of the earth; a heavy tax, undoubtedly, and one which might well justify a little grum-

bling on the part of those who had to pay it; nor could all the magnificence with which the public revenue was expended reconcile the Athenians to the heavy burdens they were called upon to bear. Indeed they not unnaturally fancied themselves oppressed by tyranny, and indulged in perpetual complaints from the time Peisistratus first ascended the throne to the day of his death; which happened in 527 B.C., about thirty-three years after he had first assumed the sovereignty, of which period, according to Aristotle, he reigned about seventeen years.[1]

In taking a retrospect, however, of the government and character of this celebrated man, it is impossible to doubt that the one was enlightened and the other humane. The ancient writers are all agreed that he made no change of any consequence in the Athenian constitution. All the laws continued in force; the general assembly, the council of state, the courts of justice, and the magistracies, respectively retained their constitutional powers; and it is known that the usurper himself obeyed a citation from the Areiopagus upon a charge of murder. His hand, it is true, lay heavy on the purses of the people in the matter of taxation. But the sums which he raised were religiously expended in the decoration and improvement of the capital, or in works of public utility; and it cannot be questioned that, although he resorted to iniquitous or contemptible expedients to obtain power, he never abused it, either for the gratification of selfishness or revenge. "Take away only his ambition," said Solon; "cure him of the lust of reigning, and there is not a man more naturally disposed to every virtue, nor a better citizen than Peisistratus." He embellished the city with a great variety of edifices; he improved and strengthened its defences; he enlarged and ameliorated its harbours; and by various acts of taste and magnificence, not less than by his attention to the cultivation of the public mind, he may be said to have fixed the muses at Athens. In a word, if he was ambitious he was also enlightened and humane; and although no one can justify the modes which he took to possess himself of power, his use of it was characterized by a moderation and patriotism which have never as yet been exemplified by any other usurper, ancient or modern; insomuch that, reviewing his character and conduct, we are almost tempted to subscribe to the sentiment expressed by the poet Claudian, *Nunquam gratior extat libertas, quam sub rege pio.*

Hipparchus and Hippias.

Peisistratus left behind him three sons, Hipparchus, Hippias, and Thessalus, all men of abilities, who shared the government among them, and behaved for a time with lenity and moderation. But though, by the mildness of their government, the family of the Peisistratidæ seemed to be fully established on the throne of Athens, a conspiracy was unexpectedly formed against the brothers, by which Hipparchus was slain, and Hippias narrowly escaped death. There were at that time living in Athens two young men, called Harmodius and Aristogeiton. The former being remarkable for his personal beauty, was, on that account, it is said, unnaturally beloved by the other, and also by Hipparchus, who, if we may believe Thucydides, actually forced him. This was vehemently resented by Aristogeiton, who, in consequence, determined on revenge, which another circumstance contributed to accelerate. Hipparchus, finding that Harmodius endeavoured on all occasions to shun him, publicly affronted the youth, by refusing permission to his sister to carry the offering of Athena, as if she had been a person unworthy of that distinction. The two young men, not daring to show any public signs of resentment, consulted privately with their friends, amongst whom it was resolved, that at the approaching festival of the great Panathenæa, when the citizens were allowed to appear in arms, they should attempt to restore Athens to its former liberty; and in this they imagined they would be seconded by the whole body of the people. But when the appointed day arrived, they perceived one of their number talking familiarly with Hippias; wherefore, dreading a discovery, they immediately fell upon Hipparchus, and despatched him with many wounds, 514 B.C. In this exploit, however, the people were so far from aiding the conspirators, that they suffered Harmodius to be killed by the guards of Hipparchus; and seizing Aristogeiton, delivered him up to the vengeance of Hippias. But they soon had reason to change their opinion, and some time afterwards paid the most extravagant honours to the memory of these conspirators; causing their praises to be sung at the great Panathenæa, forbidding any citizen to call a slave by either of their names, and erecting brazen statues to them in the agora or market-place. Several immunities and privileges were also granted to the descendants of these (so-called) patriots, and all possible means were taken to render their memory respected and revered by posterity.

Cruelty of Hippias.

Hippias being now sole master of Athens, and burning to revenge the murder of his brother, began by torturing Aristogeiton, in order to force him to disclose his accomplices. But this proved fatal to his own friends; for Aristogeiton impeaching such only as he knew to be best affected to the government of Hippias, the latter were instantly put to death without further inquiry; and when he had exhausted his list, he at last told Hippias, that he now knew of none who deserved to suffer death except the tyrant himself. Hippias next vented his rage on a woman named Leaina, who had been kept by Aristogeiton, and who was put to the torture; which, however, she had the courage to endure without making any confession. After the conspiracy was thought to be crushed, Hippias set about strengthening his government by every means he could think of. With this view he contracted alliances with foreign princes; he increased his revenues by different expedients; married his only daughter, Archedice, to Æantides, son of Hippocles, tyrant of Lampsacus; and endeavoured, by affecting various arts of popularity, to conciliate that public opinion which his excessive severities had so rudely shocked. But all these precautions proved fruitless. The lenity of the government of Peisistratus had alone supported it; and although Hippias had fewer difficulties to contend with than his father, the vehemence of his resentment on account of his brother's murder betrayed him into courses repugnant alike to sound policy and to the interests of his family, and at last proved the cause of his expulsion from power in rather less than four years after the death of Hipparchus, 510 B.C. This revolution was principally brought about by the party of the Alcmæonidæ, or adherents of Megacles. Hippias retired to Sigeum, an appanage of his family, where he contrived by every means in his power to recover his lost position at Athens, and in the end, seeing that his plans could not succeed, even assisted the Persians in the war against his native city.[2]

State of Athens.

After the expulsion of the Peisistratidæ, the Athenians did not long enjoy the tranquillity which they had promised

[1] The government of Peisistratus, as we have seen, resolves itself into three distinct periods, interrupted by two exiles. Aristotle and Herodotus both agree in this. Larcher, Clavier, and Du Fresnoy, rightly give the two exiles at 5 + 11 = 16 years; but they differ materially in the duration of the first and last tyranny; nor on this point is it easy to decide between them. (Clinton's *Fasti Hellenici*, Appendix, No. ii. p. 180; Oxford, 1824, 4to.)

[2] The Peisistratidæ were expelled before the fourth year of Hippias was completed, eighteen years after the death of Peisistratus, twenty years before the battle of Marathon, and a hundred years before the constitution of the Four Hundred. (Herodotus, v. 55; Thucydides, vi. 59, and viii. 68; Plato, *Hipparch.* p. 229; Schol. Lysistrat. 619; *Fasti Hellenici*, 16.)

Attica. themselves. They became divided into two factions; one of which was headed by Cleisthenes, chief of the Alcmæonidæ; and the other by Isagoras, a man of quality, and highly in favour with the Athenian eupatrids or nobility. Cleisthenes cultivated the people, and endeavoured to gain their affection by increasing as much as possible their power; whilst Isagoras perceiving that the popular arts of his rival would secure him an ascendancy, applied to the Lacedæmonians for assistance; at the same time reviving the old story of Megacles's sacrilege, and insisting that Cleisthenes ought to be banished as being of that person's family. Cleomenes king of Sparta readily entered into his schemes, and suddenly Cleisthenes, probably dreading the old outcry against his family, withdrew from Athens; and when Cleomenes had entered Athens at the head of an army, the people, being without a leader, were so dismayed, that they allowed the Spartan king to act as if he were absolute master. On arriving at Athens, he condemned to banishment seven hundred families, in addition to those previously sent into exile. And, not content with this, he would have dissolved the senate, and vested the government in the heads of the faction of Isagoras; but happily the Athenians were not yet degraded enough to submit to such humiliation. Taking up arms, they drove the Spartan troops into the citadel, where, after sustaining a short siege, Cleomenes surrendered, on condition that Isagoras should depart unmolested with Cleomenes and the Lacedæmonian troops; but their adherents were left to the mercy of the people, and put to death. Cleisthenes and the 700 exiled families then returned to Athens in triumph. This happened in 508 B.C.

The Spartan king, however, had no sooner withdrawn from Athens, than he formed a strong combination in favour of Isagoras; having engaged the Bœotians to attack Attica on the one side, and the Chalcidians on the other, whilst he at the head of a powerful Spartan army entered the territory of Eleusis. But this powerful confederacy was quickly dissolved. The Corinthians, who had joined Cleomenes, doubting the justice of their cause, returned home: the rest of his allies likewise began to waver; and his colleague Demaratus, the other king of Sparta, differing in opinion with Cleomenes, the latter was obliged to abandon the enterprise. The Spartans and their allies having withdrawn, the Athenians quickly routed the Bœotians and Chalcidians, and carried off a great number of prisoners, who were afterwards set at liberty on paying a ransom of two minæ a head. The Bœotians, on the other hand, immediately vowed revenge, and engaging on their side the people of Ægina, who had a hereditary hatred to the Athenians, the Æginetans landed a considerable army, and ravaged the coasts of Attica while the Athenians were occupied with the Bœotian war.

Attempt to restore Hippias. In the meanwhile Cleomenes, exasperated by his unsuccessful expedition against Attica, and anxious for an opportunity of effacing the remembrance of his defeat, produced at Sparta certain pretended oracles which he alleged he had found in the citadel of Athens while he was besieged therein, the purport of which was, that Athens would soon become a rival of Sparta. At the same time it was discovered that Cleisthenes had bribed the priestess of Apollo to cause the Lacedæmonians to expel the Peisistratidæ from Athens; which was sacrificing their best friends to those whom interest necessarily rendered their enemies. This pitiful jugglery had such an effect, that the Spartans, repenting their folly in expelling Hippias, sent for him from Sigeum, in order to restore him to his principality; but the other states refusing to countenance the projected restoration, the Spartans were forced to abandon the enterprise, Attica. and Hippias returned to Sigeum to digest his disappointment.

About this period Aristagoras the Milesian, having stirred Persian up a revolt in Ionia against the Persian king, applied to the war. Spartans for assistance; but the Spartan king either felt no sympathy with the Greeks in Asia, who had been subjected by the Persians, or because the bribes offered by Aristagoras were not large enough, declined to have anything to do with the matter. Aristagoras then proceeded to Athens, where he found willing hearers. The Athenians regarding it as a religious duty to assist their kinsmen and colonists, passed a decree to send a squadron of twenty ships to support them, under the command of Melanthus, a nobleman universally esteemed.[1] This rash action cost the Greeks very dear; for no sooner did the king of Persia hear of the assistance sent from Athens to his rebellious subjects, than he declared himself the sworn enemy of that city, and solemnly besought the deity that he might one day have it in his power to be revenged on them. But besides the displeasure which Darius had conceived against the Athenians on account of the assistance they had afforded the Ionians, he was further encouraged, by the intrigues of the ex-tyrant Hippias, to undertake an expedition against Greece. Immediately on his return from Lacedæmon, as above related, Hippias passed over into Asia; proceeded to Artaphernes, governor of the adjacent provinces belonging to the Persian king; and excited him to make war upon his country, promising to do homage to the Persian monarch provided he was restored to the principality of Athens. Apprised of this step on the part of their late tyrant, the Athenians sent ambassadors to Artaphernes, desiring permission to enjoy their liberty in peace. But the Persians returned for answer, that if they would have peace with the Great King, they must immediately consent to receive Hippias; and as the Athenians were by no means disposed to purchase the forbearance of the Persian monarch at the price of compliance, they resolved to assist his enemies by every means in their power. This resolution being made known to Darius, he commissioned Mardonius to avenge him of the insults which he thought the Greeks had offered him; but that commander having met with a storm at sea and other accidents, which rendered him unable to do anything, Datis and Artaphernes (the son of the Artaphernes above mentioned) were commissioned to chastise Grecian insolence and presumption.

Persians invade Greece. War being thus declared, the Persian commanders, fearing again to attempt doubling the promontory of Athos, where their fleet had formerly suffered, drew their forces into the plains of Cilicia, and passing thence, through the Cyclades to Eubœa, directed their course towards Athens. Their instructions were to destroy both Eretria and Athens, and to bring away the people. The first attempt was made on Eretria; and on the approach of the Persian fleet the inhabitants sent to Athens to apply for assistance. Nor did they sue in vain. With a magnanimity almost unparalleled, considering the crisis, the Athenians sent 4000 men to their aid; but unhappily the Eretrians were so greatly divided in opinion, that, though the danger was urgent, nothing could be resolved on. One party was for receiving the Athenian succours into the city; another declared for abandoning the city and retiring into the mountains of Eubœa; whilst a third was base enough to seek to betray their country to the Persians. Matters being in this hopeless state, the Athenian commanders withdrew the auxiliary force, and retiring by Oropus, escaped the destruction with which they were threatened; whilst Eretria, betrayed into the hands of the Persians, was pillaged and burned, and its inhabitants sold

[1] Herodotus, v. 37, 38, 55, 97, 98, 99. Charon Lampsacenus apud Plutarch. *Mor.* p. 861; *Fasti Hellenici*, p. 20. Aristagoras was slain in Thrace, B.C. 497.

for slaves; a fate which their cowardice and treachery richly merited.

Battle of Marathon.

On the tidings of this disaster the Athenians immediately drew together such forces as they could muster, amounting in all to about 10,000 men; and these, with 1000 Platæans who afterwards joined them, were commanded by ten general officers, with equal power, amongst whom were the illustrious names of Miltiades, Aristides, and Themistocles, men distinguished alike for their valour, their conduct, their patriotism, and their virtue. But it being generally thought that so small a body of troops would be unable to resist the formidable power of the Persians, a messenger was despatched to Sparta to entreat the immediate assistance of that state. He communicated his business to the senate in the following terms:—"Men of Lacedæmon," said he, "the Athenians desire you to assist them, and not to suffer the most ancient of all the Grecian cities to be enslaved by the barbarians. Eretria is already destroyed, and Greece consequently weakened by the loss of so considerable a place." The assistance was readily granted; but the promised succours arrived too late for the occasion which required them; and, happily for their own glory, the Athenians were obliged to fight without waiting for their arrival. In the memorable engagement on the plains of Marathon, whither Hippias had conducted the Persian host, the latter were defeated with great loss by the Athenian infantry, under the command of Miltiades, and driven to their ships, 490 B.C.[1] They then endeavoured to double Cape Sunium (Colonna), in order to surprise Athens before the army could return. But in this they were prevented by Miltiades, who, leaving Aristides with 1000 men to guard the prisoners, returned so expeditiously with the main body, that he reached the temple of Hercules before the barbarians had time to commence a serious attack on the city. In the meanwhile the virtuous Aristides discharged the trust reposed in him with the strictest integrity. Though there was much gold and silver in the Persian camp, and the tents and ships they had taken were filled with all manner of riches, he not only forbore taking anything for his own use, but exerted himself to the utmost in order to prevent others from appropriating the spoils of the enemy, which were religiously reserved for the public service of the state.

After the victory of Marathon, the inhabitants of Platæa were declared free citizens of Athens, and Miltiades, Themistocles, and Aristides were treated with all possible marks of admiration and respect. Miltiades having now reached the highest pitch of power, demanded of the Athenians a fleet of seventy ships, with which he promised to increase their empire, and the people granted his request without even knowing what expedition he wished to undertake. He first attacked Paros, where he had to avenge some private wrong, but being thwarted by the Persians, and having received a dangerous wound in his knee, he returned to Athens without having accomplished the object for which he had induced the people to fit out the fleet. The ill-feeling thus created led some person of high standing to bring an accusation against him for having deceived the people. He was sentenced to pay a fine of 50 talents, and being unable to pay, he was thrown into prison, in which he soon after died of his wounds. This termination of the career of Miltiades has often been referred to as a proof of the ingratitude of the Athenians. But it must not be forgotten that he had really deceived the people by demanding of them a fleet for the purpose of accomplishing some private object, while he made them believe that he meant to employ it in their service. He appears, in fact, to have attempted to set himself above the laws, and to continue in the free state of Athens the same mode of life which he had led as dynast in the Chersonese. Under these circumstances we may indeed pity him, but cannot admit that he fell an innocent victim to the abuse of popular liberty. His colleague Aristides, by his regulation of the affairs of the Athenian allies, and by the reforms he introduced in the constitution during the period subsequent to the battle of Marathon, gained the highest esteem and respect among his fellow-citizens. Although he was descended from an ancient and noble family, and had been in positions in which he might have acquired great wealth, yet he seems to have lived almost in indigence. Such virtue was at all times extremely uncommon at Athens, and procured for him the honourable surname of the Just. This circumstance, however, made him an object of envy with many, and Themistocles, his most powerful opponent, induced the people to send him into honourable exile by ostracism, an institution by which the Athenians were enabled to rid themselves, for a time, of any man whose influence seemed to endanger the safety of their republican constitution. Such an exile, however, was not connected either with confiscation of property or with disgrace.[2] At his trial Aristides is said to have assisted an illiterate rustic in writing his own name on one of the shells that condemned him. After his removal, Themistocles was in the undivided possession of the popular favour, and exerted all his powers to make Athens a maritime state.

Xerxes invades Greece.

About three years after the banishment of Aristides, Xerxes king of Persia sent to demand of the Greeks earth and water as tokens of submission and homage. But Themistocles, desirous to widen the breach with that monarch, put to death the interpreter for publishing the decree of the king of Persia in the language of the Greeks; and having prevailed with the several states to lay aside their animosities and provide for their common safety, he got himself elected general of the Athenian army.

When the news arrived that the Persians were advancing to invade Greece by the Straits of Thermopylæ, and that with this view they were transporting their forces by sea, Themistocles advised his countrymen to abandon the city, embark on board their galleys, and encounter their enemies while yet at a distance. But this advice being disregarded, Themistocles put himself at the head of the army, and having joined the Lacedæmonians, marched towards Tempe. But intelligence was received that the Straits of Thermopylæ had been forced, and that Bœotia and Thessaly had submitted to the Persians; and the army in consequence returned without attempting anything. In this extremity the oracle at Delphi was consulted by the Athenians, and at first returned a very alarming response, threatening them with total destruction; but after much humiliation, a more favourable answer was obtained, in which, probably by the direction of Themistocles, they were promised safety in *walls of wood*. This being interpreted as a command to abandon Athens, and place all their hopes of safety in their fleet, the greater part began to prepare for embarkation, and money

[1] For an account of the memorable battle of Marathon, with military details of the Greek armies, including the Athenian, see the article ARMY. "The Athenians who fought at Marathon," says Herodotus, "were the first among the Greeks known to have used running for the purpose of coming at once to close fight; and they were the first who withstood (in the field) even the sight of the Median dress and of the men who wear it; for hitherto the very name of Medes and Persians had been a terror to the Greeks." This honest confession seems to have given great offence to Plutarch, but it is confirmed by Plato (*in Menexen.* p. 240) and other writers of the highest authority.

[2] The ostracism of Aristides took place B.C. 483, since he was recalled τρίτῳ ἔτει Ξέρξου διὰ Θεσσαλίας ἐλαύνοντος. (Plutarch, *Aristid.* c. 8.) Some, however, think that it took place the following year; and, in fact, he seems to have been in exile at the time of the battle of Salamis. But ten months afterwards he commanded the Athenian forces at the battle of Platæa; so that his recal must have taken place between those two actions. (Herodotus, ix. 28.)

was distributed among them by the council of the Areiopagus, to the amount of eight drachmas a head; but this not proving sufficient, Themistocles publicly gave out that somebody had stolen the shield of Athena, and, under pretence of searching for the lost ægis, he seized on all the money he could find. Some, however, still refused to embark, and, understanding the oracle in its literal sense, raised fortifications of wood, resolving to wait the arrival of the Persians, and defend themselves to the last.

Capture of Athens.

The Persians having advanced to Athens soon after the inhabitants had deserted it, met with no opposition except from the few who had resolved to remain; and as they would listen to no terms of accommodation, they were put to the sword, and the city utterly destroyed. Xerxes, however, being defeated in a great naval engagement at Salamis, 480 B.C., was forced to fly with prodigious loss. Themistocles was for pursuing him and breaking down the bridge of boats which he had thrown over the Hellespont; but this advice being overruled, the crafty Athenian sent a trusty messenger to the king, acquainting him that the Greeks intended breaking down his bridge, and at the same time suggesting the propriety of his making all haste in order to prevent his retreat being cut off. This advice, though misinterpreted by some, was certainly a prudent one; as Xerxes, although he had sustained a defeat, was still at the head of an army capable of destroying all Greece; and had he been driven to despair by finding himself shut up or even too hotly pursued, it is impossible to say what might have been the event. "Make a bridge of gold for a flying enemy," is a rule which the experience of war in all ages has sanctioned.

The defeat of Xerxes at Salamis disposed Mardonius, who had been left to carry on the war by land, rather to treat with the Athenians than to fight them; and with this view he sent Alexander, king of Macedon, to Athens to propose an alliance with the republic, exclusively of the other Grecian states. But this proposal was rejected; in consequence of which Athens was a second time destroyed,[1] and the Athenians were forced to retire to Salamis. But they were soon freed from the apprehension of final subjugation by the total defeat and death of Mardonius at Platæa, where Aristides and the Athenian troops under his command particularly distinguished themselves. And, by a singular coincidence, on the same day that the battle of Platæa was fought, another division of the Persians was defeated at Mycale in Ionia, where the Athenians also behaved with more signal gallantry than any of the other Greeks. The Persians being thus disposed of, the troops who had fought at Mycale crossed over to the Chersonesus, and laid siege to Sestos, which they at length captured after an obstinate defence by the garrison; a circumstance which appears to have irritated them so much that they put both the commanders to death in the most barbarous manner. One of them, Oibazus, was sacrificed to a Thracian god; whilst the other, Artayctes, was impaled alive, and his son stoned to death before his face, on the absurd pretence that he had rifled the sepulchre of Protesilaus.

City rebuilt and fortified.

After the victories of Platæa and Mycale, in 479 B.C., the Athenians, freed from all apprehension respecting the Persians, began to rebuild their city in a more magnificent manner than ever. Throughout the Persian war, the Athenians had been most forward in opposing the barbarians; and their generals, Aristides and Cimon, displayed qualities which formed such a strong contrast with the domineering conduct of the Spartan Pausanias and the Spartan harmosts, that, with the exception of the Peloponnesians, nearly all the Greeks were desirous to place themselves under the protection of Athens, which thus acquired the supremacy in Greece. The relations of the allies, and their annual tribute, which was deposited in the temple of Apollo at Delos, was the work of Aristides, in whom all had the fullest confidence. Athens, in return, undertook the duty of protecting her allies against Persia. The constitution of Athens also underwent some changes at this time, which are ascribed to Aristides. He is said to have removed the barrier which had hitherto separated the highest from the lower classes, by throwing open the archonship and the Areiopagus to all the citizens, without any distinction of birth or wealth. This change had been prepared by the circumstances of the time; and the noble exertions of the Athenian citizens had well entitled them to be thus raised to the full enjoyment of the advantages which the state could afford. About the same time Themistocles suggested the necessity of immediately fortifying the city, so as to prevent its being again destroyed whenever the Persians might deem it expedient to invade Greece. The Lacedæmonians disrelished this project exceedingly, and remonstrated against it, upon the hollow ground, that were Athens to be strongly fortified, and the Persians to become possessed of it, it might be impossible ever to dislodge them. The Athenians were not imposed on by this shallow pretence, which was soon changed into a peremptory command not to raise their walls higher; but, considering the great power of Sparta at that time, Themistocles advised the Athenians to temporize, and to assure the Spartan envoys that the work should not be proceeded with until by a special embassy satisfaction had been given to their allies. Being, at his own desire, named ambassador in conjunction with some other Athenians, Themistocles set out alone. Arrived at Sparta, he put off from time to time receiving an audience, on the pretence that his colleagues had not yet joined him; but in the meanwhile the walls of Athens were being built with the utmost expedition, neither houses nor sepulchres being spared for materials, and men, women, children, strangers, citizens, and servants, labouring at the work without intermission. The truth, however, having at length oozed out, Themistocles and his colleagues, who had by this time arrived, were summoned before the ephori, who immediately began to exclaim against the Athenians on account of their breach of compact. But Themistocles stoutly denied the charge; his colleagues, he said, assured him of the contrary; at all events, it did not become a great state to give heed to vague rumours of this description; and if they had any doubts about the truth of his statement, the proper course would be to send deputies to inquire into the fact of the matter, whilst he should himself remain as a hostage to be answerable for the event. This plausible suggestion being agreed to, Themistocles engaged his associates to advise the Athenians to commit the Spartan ambassadors to safe custody until he should be released. Soon after Aristides and one other Athenian envoy arrived, informing Themistocles that the walls were high enough to stand a siege. Themistocles, accordingly, now dropped the mask, and bade the Spartans in future to treat the Athenians as reasonable men, who knew what they owed to themselves as well as to their countrymen. The Spartans with their wonted skill dissembled their vexation, left the Athenians to act as they saw fit, and sent Themistocles back to Athens in safety.

The following year, 478 B.C., Themistocles, observing the inconvenience of the port of Phalerum, formed the resolution of improving the Peiræus, and rendering it the principal harbour of Athens. All the three ports, Phalerum, Munychia, and Peiræus, were fortified by a double range of wall, one on the landside, and the other following the windings of the coast. This wall was 60 feet in height, and of such breadth as to allow two waggons to pass each other. Peiræus now became a town of great importance, being the residence of merchants, sailors, and foreigners, who established themselves in it for purposes of trade and commerce. By these wise and prudent measures, undertaken

[1] Athens was occupied by Mardonius ten months after its occupation by Xerxes the preceding year, B.C. 480.

Attica.

and carried through with equal energy and address, the naval power of Athens was fixed on a sure basis, and the ascendency in Grecian politics transferred from the Spartans to the Athenians.[1]

Themistocles banished.

The victory of Salamis and his prudent management of the affairs of Athens had raised Themistocles to a giddy height, which made him proud, indiscreet, and rapacious, and drew upon him the charge of perfidy, avarice, and cruelty. His acts of selfishness made many persons his enemies, and the Spartans never forgiving him the manner in which he had thwarted their schemes, were ever active in rousing the jealousy and fears of his countrymen. In addition to all this, younger men were rising and taking his place in popular favour. The people accordingly were easily persuaded to consider him a dangerous person, and condemned him to a temporary exile by ostracism. He went to Argos, where he was still residing, 471 B.C., when the condemnation of the Spartan Pausanias for high treason brought ruin upon the head of Themistocles also. The Spartans charging him with being an accomplice of Pausanias, demanded of the Athenians to put him to death. His enemies at Athens rejoiced at this opportunity of crushing him, and officers were sent out to arrest him. But he fled and reached Ephesus in safety. Thence he proceeded to the court of Persia, where, by his prudence and cunning, he soon became a general favourite. King Artaxerxes at length sent him to Western Asia, where he was enabled by the king's munificence to maintain a sort of princely rank. At length, however, he is said to have made away with himself, because he felt unable to fulfil the promises he had made to the king.

Exploits of Cimon.

But the war with Persia was not yet discontinued, and about the end of the 77th Olympiad, the Athenians equipped a fleet to relieve certain Greek cities in Asia, subject to the Persians, and gave the command of it to Cimon, the son of Miltiades by a daughter of the king of Thrace. Cimon had already tasted the temper of his countrymen, having been thrown into prison for his father's fine, from which he was released by Callias, whom his sister Elpinice had married on account of his great wealth, procured, it is said, by no very honourable means. But he nevertheless accepted of the command, and gained such immense booty in this expedition, that the Athenians were thereby enabled to lay the foundation of that longimural inclosure which united the port to the city; as also to adorn the Agora with palm-trees, and beautify the Academy with delightful walks and fountains. Soon after this expedition, the Persians having invaded the Chersonesus, and made themselves masters of it, with the assistance of the Thracians, Cimon was hastily sent against both. He had only four ships under his command; but with these he captured thirteen of the Persian galleys, and reduced the whole of the Chersonesus; after which he attacked the Thracians, who had made themselves masters of the gold mines situated between the rivers Nessus and Strymon, and speedily obliged them to yield. But Cimon was as wise and politic as he was brave. Many of the Greek states, in virtue of the general tax established by Aristides with the view of providing a fund for the common defence, were bound to furnish men and galleys, as well as to pay for their support. But when they saw themselves exposed to danger from the Persians, most of them evinced an unwillingness to furnish their contingent of men. This exasperated the Athenian generals, who, finding them obstinate in their refusal, were for having immediate recourse to force; but Cimon overruled this proposal, permitted such as were desirous of staying at home to remain, and accepted a sum of money instead of a galley completely manned; by which means he inured the Athenians, whom he took on board his galleys, to hardship and discipline, whilst the allies, who remained at home, became enervated through idleness, and, from being confederates, dwindled into tributaries or subjects.

Attica.

Cimon banished.

Cimon had gained great wealth both to the state and to himself; but in his public character he had acted with unimpeached integrity, and as a private citizen he had dedicated his wealth to the most laudable purposes. He had demolished the inclosures about his grounds and gardens, permitting every one to enter and take what fruits they pleased; and he had kept open table, where both rich and poor were plentifully entertained. If he met a citizen in a tattered suit of clothes, he made some of his attendants exchange with him; or if the quality of the person rendered such a kindness unsuitable, he caused a sum of money to be privately given him. All this excessive liberality, however, was as degrading to the benefactor as to the benefited, and was nothing but the means by which he endeavoured to win popularity among the people. The nobles, to whose order Cimon belonged, had lost the power of oppressing the people, and now found it expedient to court them in every possible way for the purpose of securing to themselves all the power that yet remained to them. Pericles, his great rival, unable to cope with Cimon's profusion, became the author of a series of measures, all of which tended to provide for the subsistence and gratification of the poorer classes at the public expense. The apparent neglect of Cimon in not conquering a district in the north of the Ægean was the cause of an accusation against him, in which Pericles was requested to take the lead; but he honourably declined doing so, because in his eyes the charge was unfounded. The result of this trial is not certain; for according to some Cimon was acquitted, while according to others he was sentenced to pay a fine of 50 talents. Soon afterwards, however, the aristocratic party, of which Cimon was the leader, became involved in a serious struggle with the democratic party, led by Pericles: the latter having succeeded in reducing the power of the Areiopagus, the last stronghold of the aristocracy, it was thought advisable, for the public safety, to remove Cimon for a time from Athens by ostracism.

War with Sparta.

The Athenian power had now risen to such a height that all the states of Peloponnesus looked upon the republic with a jealous eye, and were continually watching for opportunities of making war upon it when engaged in troublesome affairs, or hard pressed by other enemies. These attempts, however, so far from lessening, generally contributed to increase the power of the Athenians. But in the year B.C. 458, the republic entered into a war with Sparta, which eventually proved nearly as fatal to the state as to the city. The Spartans had sent a considerable army to assist the Dorians against the Phocians; and on their return commenced intriguing with the aristocratic party at Athens. This led the Athenians to the determination not to wait till it was too late. Having therefore engaged the Argives and Thessalians as confederates, they posted themselves on the isthmus, so that the Spartan army could not return without encountering them. The Athenians and their confederates amounted to 14,000, and the Spartans to 11,500 men. The Lacedæmonian general, however, unwilling to hazard a battle, turned aside to Tanagra, a city of Bœotia, where some of the Athenians who were favourable to aristocracy entered into a correspondence with him. But before their designs were ripe for execution, the Athenian army marched with great expedition to Tanagra, and instantly made arrangements for the attack. They were however defeated with great loss, in consequence of the perfidy of the Thessalians, who in the midst of the battle went over to the enemy. Another engagement soon followed, in which both armies suffered so much that they were glad to conclude a short truce, that each might have time to recruit their shattered forces. But the

[1] For an account of the fortifications of the capital of Attica, the Long Walls, and the defences of Peiræus, Phalerum, and Munychia, see article ATHENS.

Attica.

scale of fortune soon turned in favour of the Athenians. The Thebans, who had been deprived of the command of Bœotia on account of their having sided with Xerxes, were now restored to it by the Lacedæmonians. At this the Athenians were so greatly displeased that they sent an army under Myronides the son of Callias into Bœotia to overturn all that had been done. That general was encountered by the Thebans and their allies, who composed a numerous and well-disciplined army; but although the Athenian army was but a handful in comparison to that of their enemies, Myronides gained a victory over the allies, which, in a purely military point of view, may perhaps be considered as more glorious than either that of Marathon or of Platæa. In these battles they had fought against the effeminate and ill-disciplined troops of Persia; but now they encountered and defeated a superior army composed of the bravest Greeks. After this victory Myronides marched to Tanagra, which he took by storm, and afterwards razed to the ground. He then plundered Bœotia; defeated another army which the Bœotians had drawn together to oppose him; next fell upon the Locrians; and having penetrated into Thessaly, chastised the inhabitants of that country for having revolted from the Athenians; after which he returned to Athens laden alike with riches and with glory.

Death of Cimon.

About this time, 457 B.C., Cimon was recalled from banishment by the will of the people, and soon after fell to his old employment of warring against the Persians; having nothing less in view, according to Plutarch, than the conquest and subjugation of the whole Persian empire. But, however this may be, the Great King, finding he could have no rest whilst he continued in a state of hostility with the Athenians, sent instructions to his generals, Artabazus and Megabizus, to conclude, if possible, a treaty of peace; which, after much discussion, was at length effected upon the following conditions: 1. That the Greek cities in Asia should be free, and governed by their own laws. 2. That the Persians should send no army within three days' journey of the sea. 3. That no Persian ship of war should sail between Phaselis in Pamphylia and the Chelidonian islands off the coast of Lycia. Whilst this treaty was pending, Cimon died B.C. 449, but whether of sickness or of a wound which he had received in battle remains unknown. This so-called peace of Cimon is probably a mere fable, which arose out of the recollection of the glorious exploits of that general. All the subsequent history shows that such a state of things as the terms of this peace imply never existed. The story does not appear to have assumed a distinct form until the time of the rhetorician Isocrates.

Truce with Sparta.

One thing, however, is certain, that after the death of this remarkable personage, the Athenian affairs began to fall into confusion. It was now the misfortune of the republic to be alike hated by her enemies and by her allies; and hence the latter missed no opportunity of throwing off their allegiance when they thought they could do so with impunity. The Megarians, for instance, who had long been under the protection of Athens, thought proper to disclaim all dependence on their ancient protectrix, and to have recourse to Sparta, with which they entered into a strict alliance offensive and defensive. Exasperated at this proceeding, and determined to punish the ingratitude of their former allies, the Athenians ravaged the country of the Megarians—a step which soon brought on a renewal of the Lacedæmonian war, which had been suspended rather than terminated. But Pericles procured the return of the first Lacedæmonian army without bloodshed, by bribing Cleandridas, the young king of Sparta's tutor; and the Lacedæmonians, finding it was not for their interest to carry on the war, concluded a truce or pacification with the Athenians for the period of thirty years,[1] 445 B.C.

Attica.

Six years after the conclusion of the peace between Athens and Sparta, a war broke out between the Samians and Milesians, about an insignificant town situated under Mount Mycale, in Ionia. In this war the Athenians took part, their protection having been solicited by the Milesians; and the island of Samos was reduced by Pericles, who established there a democracy, and left an Athenian garrison. He was no sooner gone, however, than the aristocratic party rose in arms and expelled the garrison; but Pericles quickly returning, besieged and took their city, demolished their walls, and fined them in the whole expense of the war, part of which he obliged them to pay down, and took hostages for the remainder.[2] This happened in 444 B.C.

Reduction of Samos.

Corcyræan war.

This insignificant contest was almost immediately followed by a war between the Corcyræans and Corinthians, which arose out of the following circumstances. An intestine broil breaking out in the little territory of Epidamnus, a town of Illyricum, founded by the Corcyræans, one party applied for aid to the Illyrians, and the other to the Corcyræans. But the latter having neglected the matter, Corinth was appealed to, as the Corcyræans were originally a colony from that place; and the Corinthians, partly out of pity for the Epidamnians, partly from dislike to the Corcyræans, despatched a considerable fleet to the assistance of the former, by which means the party which had appealed to Corinth gained the ascendency. This being resented by the Corcyræans, they sent a fleet to Epidamnus to support the exiles; but although this fleet began to act offensively on its entering the port, the chief commanders had instructions to propose terms of accommodation. To these, however, the Corinthians refused to accede; and next year the Corcyræans defeated the Corinthians and their allies at sea, took Epidamnus by storm, and wasted the territories of the allies of the Corinthians, 434 B.C. The latter, therefore, began to make great preparations for carrying on the war, and pressed their allies to imitate their example, that they might be in a condition to retrieve the honour they had lost, and to humble the ungrateful colony which had thus insulted the metropolitan city.

When the Corcyræans became acquainted with these proceedings, they despatched envoys to Athens to sue for aid; and these were quickly followed by others from Corinth on the same errand. At first the Athenians inclined to favour the Corinthians, but the next day they resolved to support the Corcyræans; contenting themselves, however, with entering into a defensive alliance with that little state, and furnishing the Corcyræans with ten galleys under the command of Lacedæmonius, the son of Cimon. But this determination did not retard the preparations of the Corinthians, who, as soon as the season permitted, sailed for the coast of Corcyra with a fleet of 150 ships, under the command of Xenoclides, assisted by four other Corinthian admirals; each squadron of their allies being commanded by an admiral of its own. The Corcyræan and Athenian fleet amounted to 120 sail; but the Athenians had orders to give as little assistance as possible. A brisk action ensued, in which the Corcyræan right wing broke the left of the Corinthian fleet, and drove some of the ships on shore; whilst the Corinthian ships in the right wing defeated the Corcyræan ships opposed to them. Next day preparations were made on both sides for renewing the battle; but twenty ships arriving opportunely from Athens to the assistance of the Corcyræans, turned the scale against the Corinthians, who therefore declined the combat, 432 B.C.

As soon as the Corcyræan war broke out, the Athenians

[1] On the subject of the thirty years' truce, concluded B.C. 445, the reader may consult and compare Andocid. *de Pace*, p. 14, 24; Æschin. *Fals. Leg.* p. 23, 51. It was about this time that Pericles began to assume the sole direction of affairs.

[2] Thucydides, i. 117.

Attica.

sent orders to the citizens of Potidæa to demolish part of their wall, to send back the magistrates they had received from Corinth, and to give hostages for their own behaviour. The Potidæans, however, refused to comply with this demand; upon which the Athenians despatched a considerable fleet against them under the command of Callias, a man celebrated for his courage; whilst the Corinthians, on the other hand, sent one Aristeus, with a considerable body of troops, to the assistance of the city. An engagement ensued, in which the Athenians were victorious, but their brave general fell in the action. Phormio, who succeeded to the command on the death of Callias, then invested the city in form, and blockaded its harbour with his fleet; but the Potidæans, dreading the vengeance of the Athenians, made a most obstinate defence, at the same time warmly soliciting the Corinthians to perform their promises, and to engage the rest of the states of Peloponnesus to take part in their quarrel.

Reparation demanded.

Meanwhile the Lacedæmonians having heard the complaints of the Corinthians and other small states of Greece, against the Athenians, sent ambassadors to Athens, to demand reparation for the injuries done to these states, and, in the event of refusal, to denounce war. The terms demanded were, first, that all Athenians who were allied to the family of Megacles should be expelled from Attica; secondly, that the siege of Potidæa should be raised; thirdly, that the inhabitants of Ægina should be left free; and lastly, that a decree prohibiting the Megarians from resorting to the ports and markets of Athens should be revoked, and all the Grecian states under the dominion of Athens set at liberty.

Refused.

By the persuasion of Pericles, however, these degrading terms were rejected; and while the right arbitrarily claimed by the commonwealth of Sparta to interfere in the concerns of the other Greek states, in the character of a lord-paramount, was peremptorily denied, an accommodation was proposed upon the fair principles of equality and reciprocity. In recommending the measure which he suggested for the adoption of his countrymen, this celebrated statesman argued that, whatever the Lacedæmonians might pretend as to the complaints of the allies, the true ground of their resentment was the prosperity of the Athenian republic, which they had always hated, and now sought an opportunity of humbling; and that it must be owing to the Athenians themselves if this design succeeded, because, for many reasons, Athens was better able to engage in a long and expensive war than the Peloponnesians. He then laid before the people an exact account of their circumstances, reminding them that the treasure brought from Delos amounted to no less than 10,000 talents; that although 4000 of these had been expended on the magnificence of their citadel, 6000 still remained in their coffers; that they were also entitled to the subsidies payable by the confederate states; that the statues of their gods, the spoils of the Persians, and other valuable property, were worth immense sums; that many private individuals had amassed vast fortunes; that considering the extent of their trade and commerce, they might calculate upon a certain annual increase of wealth; that they had on foot an army consisting of 12,000 men, besides 17,000 in their colonies and garrisons; that their fleet amounted to 300 sail; and finally, that the Peloponnesians, with whom they might be called to contend, had none of these advantages, and, as compared with the Athenians, were nearly destitute of all those resources which constitute the sinews of war. For these reasons he proposed, as at once the most consistent and most equitable satisfaction that could be given, to reverse the decree against Megara, provided the Lacedæmonians agreed to accede to the principle of reciprocity in favour of the Athenians and their allies; to consent to leave all those states free which were acknowledged as such at the conclusion of the last peace with Sparta, provided the latter state also agreed to give freedom to all the states which were under their dominion; and, finally, to submit to arbitration all disputes which might in future arise between the parties to this arrangement. He concluded by advising them to hazard a war in case these terms were rejected; telling them that they should not think they ran that hazard for a trifle, or retain a scruple in their minds as if a small consideration moved them to it, because on this matter depended their safety, and the reputation of their constancy and resolution. If they yielded in this, the next demand of the Lacedæmonians would be still more extravagant; for having once discovered that the Athenians were to be acted upon by fear, they would thence conclude that nothing could be denied them, whereas a stout resistance in the present case would teach them to treat Athens in future upon terms of reciprocity.

Attica.

Peloponnesian war.

The firm attitude which Athens assumed on this occasion, under the guidance of her most illustrious statesman, may be considered as the origin of the Peloponnesian war, which makes so prominent a figure in ancient history. The immediate preliminary to general hostilities, however, was an attempt of the Thebans to surprise Platæa in 431 B.C. With this view they in the depth of night sent 300 men to assist those of the Platæans whom they had drawn over to their interest, in making themselves masters of the place. But although the design succeeded very well at first,—the Platæans, who had promised to open the gates, keeping their words exactly, so that they instantly obtained possession of the city,—yet the other party, perceiving the smallness of the number they had to contend with, unanimously rose upon them, killed a great many, and forced the remainder to surrender themselves prisoners of war. The Thebans sent a reinforcement to assist their countrymen, but it arrived too late to be of any service, and the whole were ultimately obliged to withdraw. As soon as the Athenians were apprised of this attempt, they immediately despatched a considerable convoy of provisions to Platæa, together with a numerous body of troops for the purpose of escorting the wives and children of the inhabitants to Athens. This attempt leaving no doubt that all hopes of accommodation were at an end, both parties began to prepare in good earnest for war. Most of the Grecian states inclined to favour the Spartans, partly because the latter assumed the character of deliverers of Greece, and partly also because many of the states either had been, or feared they would be, oppressed by the Athenians. Accordingly, the whole of the Peloponnesians except the Argives and part of the Achæans made common cause with the Spartans; whilst, on the continent of Greece, the Megarians, Phocians, Locrians, Bœotians, Ambraciots, Leucadians, and Anactorians, declared for the Athenians; as also did the Chians, Lesbians, Platæans, Messenians, Acarnanians, Corcyræans, Zacynthians, Carians, Dorians, Thracians, and all the Cyclades, excepting Melos and Thera, together with Eubœa and Samos.

First year

The Peloponnesian war commenced in the year B.C. 431. The Lacedæmonian army, consisting of no less than 60,000 men, assembled on the isthmus, and, after a vain attempt at negotiation, the campaign opened. The Lacedæmonian army was commanded by Archidamus, king of Sparta; that of the Athenians by Pericles, with nine generals under him. Soon after the opening of the campaign, the Spartan force entered Attica and committed horrible ravages; Pericles having no force capable of opposing it, and steadily refusing to engage on disadvantageous terms, although prodigious clamours were in consequence raised against him by his countrymen. The invaders, however, had no great reason to boast of the advantages they had gained; for an Athenian fleet ravaged the coasts of Peloponnesus, whilst another infested the Locrians, expelled the inhabitants of Ægina, and repeopled the island from Athens and Attica. Cephalonia,

Attica. and some towns in Acarnania and Leucas which had declared for the Lacedæmonians, were also reduced; and in the autumn, when the Peloponnesians had retired, Pericles entered the Megarian territory, which he laid waste with fire and sword, in revenge for the devastation committed in Attica.

Second year. But the spring of the second year proved signally disastrous to Athens; for a dreadful plague carried off great numbers of the citizens, whilst the Peloponnesians, under Archidamus, wasted every thing abroad. In the midst of all these calamities, however, the firmness of Pericles remained unshaken; and he would suffer none of his countrymen to stir from the city, either to escape the plague, which committed horrible ravages within the walls, or to assail the enemy, who desolated the country without.[1] He meditated a deeper game, namely, an inroad into the enemy's territory, which in fact had been left completely uncovered by the attack upon Attica. With this view he caused a large fleet to be equipped, on board which he embarked 4000 foot and 300 horse, and immediately set sail for Epidaurus. This diversion produced the desired effect, in compelling the enemy to withdraw from Attica; but in other respects the expedition failed on account of the plague, which committed so great havoc among his men, that Pericles brought back to Athens only 1500 of the 4300 composing the expedition. By this disaster the Athenians were thrown into utter despair, and immediately sued for peace; but the Spartans refusing to accede to any terms of accommodation, their despair gave place to fury against their great statesman and commander, whom they dismissed from their service, and amerced in a heavy fine. And, as if this had not been enough, at the same time that Pericles experienced the ingratitude of his country, the plague carried off his children and nearly the whole of his kindred, leaving him almost alone in the world, childless and forsaken. This accumulation of misfortunes preyed deeply on his spirits and overwhelmed him with melancholy, in consequence of which he secluded himself for a time entirely from public view. But through the persuasion of Alcibiades and other friends, he was at length induced to show himself to the people; who, ever inconstant, and generally more prompt to pardon than to condemn, received him with acclamations of joy. The first use Pericles made of his recovered popularity was to procure the repeal of the law which he had himself caused to be enacted, whereby all Athenians of half blood were disfranchised of their natural liberty, and reduced to the state of aliens; a measure which was not altogether disinterested on his part, as he was thereby enabled to enrol in the list of citizens his only remaining son by a Milesian mother, whom the operation of the law in question had of course bastardized. But this was destined to be one of the last public acts of the great Athenian statesman and patriot.

Third year. The third year of the Peloponnesian war was chiefly remarkable for the death of Pericles, who at length fell a victim to the plague, which had already desolated his house, but who left behind him a name that will never die.[2] Platæa was also besieged by Archidamus, but without success; for although the greater part of it had been set on fire, the Platæans resolved to submit to every extremity rather than abandon the Athenian cause. In the end, therefore, the king of Sparta was obliged to convert the siege into a blockade, and to return to Peloponnesus. Attica.

Fourth year. In the following summer the Peloponnesians under Archidamus again invaded Attica, wasting everything with fire and sword; and at the same time the whole island of Lesbos, except the district of Methymna, revolted against the Athenians. In the meanwhile Platæa was strictly blockaded, and its inhabitants being reduced to the greatest extremity from want of provisions, the garrison came to the resolution of forcing a passage through the enemy's lines. When the moment arrived, however, for carrying this design into execution, many of them became intimidated; but the greater number persisted in their resolution, succeeded in their gallant attempt, and above 200 reached Athens in safety.

Fifth year. In the beginning of the fifth year the Peloponnesians sent forty ships to the relief of Mitylene, which the Athenians had invested after the revolt of Lesbos; but this effort proved unavailing, since the place had surrendered before the fleet could come to its assistance. Paches, the Athenian commander, then drove off the Peloponnesian fleet; and returning to Lesbos, sent the Lacedæmonian agent, whom he found in Mitylene, together with a deputation, to Athens. On their arrival the Lacedæmonian was immediately put to death; and in a general assembly of the people, it was resolved, on the proposal of Cleon, that all the Mitylenians who had attained to manhood should also be put to death, and the women and children sold as slaves. But the next day this cruel decree was revoked, and a galley despatched to countermand the sanguinary order. It arrived just in time to save Mitylene. Only about a thousand of the principal insurgents were put to death; the walls of the city were however demolished, their ships taken away, and their lands divided among the Athenians, who let them again to their former proprietors at a nominal rent. About this time also the Platæans who had failed in the attempt to break through the enemy's lines surrendered at discretion, and were cruelly put to death by the Lacedæmonians, who sold their women as slaves. The city was soon after razed by the Thebans, who left only an inn to show where it stood; but the fame of Platæa induced Alexander the Great afterwards to rebuild it on a more extensive scale.

Sedition of Corcyra. In this year also happened the famous sedition of Corcyra, proverbial for the horrors with which it was accompanied. We have already seen that the dispute between the Corcyræans and Corinthians was mainly instrumental in bringing on the Peloponnesian war, one of the most protracted and sanguinary contests of ancient times. At the commencement of this struggle a great number of Corcyræans were carried as prisoners to Corinth, where the chief of them were well treated, and the remainder sold as slaves. The motive of this conduct on the part of the Corinthians was a design they had formed of engaging these Corcyræans to influence their countrymen to join the Corinthians and their allies. With this view the latter treated them with all imaginable lenity and tenderness, endeavouring to instil into their minds a hatred of democratic government; after which they were informed that they might obtain their liberty upon condition of exerting their influence at home in favour of the allies, and to the prejudice of Athens. This the Corcyræans readily promised and endeavoured to perform; and

[1] In this campaign the Peloponnesians remained forty days in Attica, burning and destroying without, while the pestilence was raging within the city, and while the Athenians seemed abandoned to utter despair. For an account of this memorable plague see Thucydides, ii. 47, whose description has been often imitated, but never equalled, far less surpassed. That which approaches nearest to it in horrible truth and picturesqueness of delineation is the description of the plague in Egypt, and also in the prison of the Seraglio at Constantinople, contained in the novel entitled *Anastasius, or Memoirs of a Modern Greek*; a work which displays greater talents, and gives a more vivid and faithful picture of society and manners in the countries of the Levant, than all the books which have yet been written on the subject.

[2] Plutarch (*Pericl.* c. 16) says that Pericles was engaged in public affairs forty years, and performed certain functions during fifteen; but the fifteen are evidently included in the forty. Accordingly, Cicero (*Orat.* iii. 34) says, "Quadraginta annos præfuit Athenis;" and from other authorities we learn that he began to appear in public affairs about the year B.C. 469, and to have the sole direction about the year B.C. 444; so that he could not have exceeded fourscore at the time of his death, which took place in B.C. 429.

Attica.

at first the partisans of aristocracy so far prevailed, that, assisted by a Peloponnesian fleet, they murdered such of the opposite party as fell into their hands. But the Athenians having despatched first one fleet and then another to the assistance of their friends, the Peloponnesians were forced to withdraw, leaving the aristocrats at the mercy of the democratic party; who, having thus gained the ascendency, literally exterminated their antagonists with circumstances of horrible atrocity. Nor was this all. For, the example once set, the several states of Greece in their turn experienced similar commotions, which were invariably fermented by agents of Sparta or of Athens; the former endeavouring to establish an aristocratic and the latter a democratic form of government, wherever their influence happened to prevail.

Sicilian war.

While the Athenians were thus engaged in a contest in which they were already overmatched, they foolishly rushed into a new one, which in the end proved more disastrous than any in which they had yet embarked. The inhabitants of Sicily were, it seems, divided into two factions; the one called the Doric, at the head of which was Syracuse; the other the Ionic, at the head of which was Leontini. But the Ionic faction finding itself too weak to contend with its rival without foreign aid, sent Gorgias of Leontini, a celebrated orator, sophist, and rhetorician, to Athens to apply for assistance; and he by his fine speeches so captivated the multitude, the Μέγα Θρέμμα, or Great Beast (as the populace were sometimes contemptuously styled in private, by those who did not scruple to pander to their worst passions in public), that they rushed headlong into a war which they were unable to maintain while engaged in a death-struggle with nearly all the states of the Peloponnesus. Accordingly, bewrayed by the wily sophist,[1] and probably enticed by the hope of effecting the conquest of Sicily, they despatched a fleet to the assistance of the Leontines, under the command of Laches and Chabrias; and this had no sooner sailed than another destined for the same service was begun to be fitted out. In the mean time the plague continued its ravages to such an extent that in the course of this year four thousand citizens, and a much larger number of the lower class of people, fell victims to its fury.

Sixth and seventh years.

The sixth year of the Peloponnesian war was not remarkable for any great exploit. Agis, the son of Archidamus, king of Sparta, assembled an army in order to invade Attica; but was prevented from doing so by earthquakes, which shook almost every part of Greece, and produced general consternation. The next year, however, he entered Attica with his army; whilst the Athenians, on their part, sent a fleet, under the command of Demosthenes, to infest the coasts of Peloponnesus. As this fleet passed the coast of Laconia, the commander observed that the promontory of Pylos, which was joined to the continent by a narrow neck of land, had before it an island about two miles in circumference, which, though barren in itself, nevertheless contained an excellent harbour, sheltered from all winds either by the headland or isle, and capable of admitting the most numerous fleets; circumstances which led him to conclude that a garrison left here would alarm the Peloponnesians, and induce them to think rather of protecting their own country than of invading that of their neighbours. Accordingly, having raised a strong fortification, he established himself in the post, reserving five ships of war for its defence; and ordered the rest of the fleet to proceed to its intended destination. On the news of this event the Peloponnesian army immediately returned to besiege Pylos, and soon made themselves masters of the harbour, as well as of the island of Sphacteria, which was taken by a chosen body of Spartans. They then made a vigorous attack upon the fort, hoping to carry it before succours could arrive; but Demosthenes and his garrison made an obstinate defence; and an Athenian fleet arriving in the interval, relieved the besieged from all apprehensions on account of the superior force of the enemy. Battle was immediately offered; but as the Peloponnesian fleet declined the challenge, the Athenians sailed boldly into the harbour, and sunk or destroyed most of the enemy's ships, after which they besieged the Spartans in Sphacteria. Alarmed at finding the war carried into their own territory, the Peloponnesians now began to treat with their enemies; and whilst the negotiations were carrying on at Athens, a cessation of hostilities was agreed to, upon the condition that the Peloponnesians should in the mean time deliver up all their ships, but that in the event of the treaty not taking effect, these should be immediately restored. In as far as regards the negotiations, the Athenians, having heard the propositions of the Spartan plenipotentiaries, were at first strongly inclined to put an end to this ruinous and destructive war, all the evils of which had been so greatly aggravated by the dreadful pestilence which at the same time ravaged the city of Athens and part of the territory of Attica. But the demagogue Cleon, a fiery and headstrong man, persuaded his countrymen to insist on the most unreasonable terms; and as the confederates were by no means so far reduced as to suffer the Athenians *pacis imponere morem*, to dictate terms of peace, the plenipotentiaries withdrew, and by doing so, of course put an end to the armistice. The Peloponnesians then demanded the restoration of their vessels, conformably to the stipulation above mentioned; but the Athenians refused to deliver them up, on pretence that the former had violated the truce. Hostilities, therefore, were immediately recommenced on both sides; and the Lacedæmonians attacked the Athenians at Pylos, while the latter attacked the Spartans at Sphacteria. But the Lacedæmonians, though only a handful of men, and under every imaginable discouragement, defended themselves with so much bravery that the siege proceeded very slowly; and the people of Athens becoming uneasy at its duration, began to wish they had embraced the offers of the Spartans, and to rail vehemently against Cleon, who had been primarily instrumental in occasioning their rejection. To excuse himself, however, Cleon affirmed it would be an easy matter for the general of the forces which they were then sending to attack the Spartans in the isle, and reduce them at once. Nicias, who had just been appointed to the command, replied that if Cleon believed he could perform such wonders, he would do well to repair to the scene of action in person. Cleon, compelled to sustain his part, rejoined without hesitation that he was ready to go with all his heart; upon which Nicias caught him at his word, and declared that he had relinquished his command. Startled at this renunciation, the speech-maker protested that he was no general; but Nicias tauntingly assured him that he might some day become one; and the people amused with the controversy, held Cleon to his word. He then advancing, told them he was so little afraid of the enemy, that, with a very inconsiderable force, he would undertake, in conjunction with that already at Pylos, to bring to Athens in twenty days the Spartans who had given them so much trouble. The people laughed at this apparent gasconade; but having furnished him with the troops he desired, he, to the infinite surprise of every one,

Attica.

[1] Diodorus, xii. 53. See also Pausanias, vi. 17, 5, and Philostratus *in Vit. Gorg.* This celebrated artist in the dangerous craft of making the worse appear the better reason, would seem to have been a singular specimen of "health and longevity:" for, according to Philostratus, λέγεται ὁ Γοργίας ἐς ὀκτὼ καὶ ἑκατὸν ἐλάσαι ἔτη; but the sounder opinion seems to be, that he was born about B.C. 485, and died soon after B.C. 380, at the age of 105 or 106. He was in reputation as a sophist and rhetorician for nearly fourscore years. (*Fasti Hellenici*, p. 63.)

brought the Spartans prisoners to Athens within the time he had specified.[1]

Eighth year.

In the eighth year of the war Nicias reduced the island of Cythera on the coast of Laconia, and Thyræa, a frontier territory, which had been given to the Æginetans when expelled from their own country by the Athenians. In Sicily, Hermocrates of Syracuse, having persuaded the inhabitants of the island to adjust their differences without foreign interference, the Athenian generals returned home; a step which so greatly displeased their countrymen, that two of them were banished, and the third was sentenced to pay a heavy fine. The Athenians, under the conduct of Hippocrates and Demosthenes, next laid siege to Megara; but Brasidas, a Spartan general, coming to its relief, a battle ensued, which, though indecisive in its result, gave the Lacedæmonian faction an ascendency in Megara, and forced many who had favoured the Athenians to withdraw. In Bœotia some commotions were raised in favour of the Athenians; but their generals Hippocrates and Demosthenes being defeated by the Lacedæmonian party, all hopes ceased of the Athenian power being established in this district of Greece.[2]

Ninth year.

In the ninth year the Spartans made new proposals of peace, which the Athenians were now more inclined to accept than formerly; and finding their affairs much unsettled by the loss of Amphipolis, which had been reduced by Brasidas, a truce for a year was agreed on, while negotiations were immediately opened for restoring a general peace. But this pacific scheme was soon overthrown by a misunderstanding, arising out of an occurrence purely accidental, and the war was in consequence renewed.

Nician pacification.

The following year commenced with an attempt by Brasidas upon Potidæa; but this having failed, the Athenians began to recover some courage; and the truce expiring on the day of the Pythian games, Cleon advised the Athenians to send an army under his own command into Thrace. They agreed to this proposal, and immediately fitted out a force, consisting of 1200 foot and 300 horse, all Athenian citizens, embarked on board thirty galleys, of which the demagogue took the command. Brasidas was inferior in numbers to his opponent; but, observing that the Athenian commander was careless, and neglectful of discipline, the Spartan suddenly attacked him, and routed his army with the loss of half its numbers, while that of the assailants amounted to only seven killed and a few wounded. In this encounter, which appears to have been a complete surprise, the commanders on both sides were slain; and although the Athenians might well spare their general, whom impudence and accident had invested with a military command, the death of their brave leader was a serious loss to the Spartans, who, in fact, lamented him more than the Athenians did the loss of the battle. In consequence of this event, however, the latter were now much more disposed than formerly to listen to terms of accommodation. Amongst the Spartans, too, there was a party, at the head of whom was Plistoanax, their king, who earnestly wished for peace; and as Nicias laboured no less assiduously at Athens to bring about this desirable event, a peace was at last, 421 B.C., concluded between the two nations for the period of 50 years.[3] The conditions were, a restitution of places and prisoners on both sides, with the exception of Nisæa, which was to remain in the hands of the Athenians, who had taken it from the Megarians, and of Platæa, which was to continue in possession of the Thebans, who could not possibly give it up without uncovering the whole of their territory. The Bœotians, Corinthians, and Megarians, refused to be included in this peace; but the rest of the allies acquiesced; and being accordingly ratified, it received the name of the Nician pacification, from that of the general who had been mainly instrumental in restoring the blessing of peace to his country.

New misunderstandings.

But although peace was nominally established, tranquillity was far from being restored. Dissatisfied with the treaty on various grounds, several states of the Peloponnesus, headed by Argos, immediately commenced organizing a new confederacy; even the Lacedæmonians found it impossible to fulfil exactly the stipulations of the agreement; and the town of Amphipolis in particular peremptorily refused to return under the government of Athens; for which reason the Athenians also refused to evacuate Pylos. In the course of the winter fresh negotiations were opened, but nothing definite was agreed upon, and the time passed in mutual complaints and recriminations. At Athens, in particular, the flame of discontent was artfully fanned by Alcibiades, who now began to rival Nicias in public favour, and who, perceiving that the Lacedæmonians paid their court principally to his rival, took every opportunity of incensing his countrymen against that nation. On the other hand, Nicias, whose reputation was concerned in maintaining the treaty inviolate, used his utmost endeavours to bring about a reconciliation, and even undertook a journey to Sparta, in the hope of effecting an accommodation; but, most unhappily, the artifices of Alcibiades, added to the turbulent and haughty disposition of both nations, rendered all his efforts unavailing, and at length satisfied him that a renewal of the war was inevitable. If the intrigues of that remarkable man, however, were mainly instrumental in bringing about a rupture, it cannot be denied that he took the most prudent methods for insuring the safety of his country. With this view he entered into a league with the Argives for the long term of a hundred years; he then marched into the territories of that state at the head of a considerable force; and he exerted all his influence, both at Argos and at Patræ, to persuade the people to connect their cities with the sea by means of walls, in order to facilitate the landing of succour, when it might be necessary, by the Athenians. But, though vigorous preparations were now made for a renewal of the war, nothing of any consequence was undertaken this year; if we except an attempt by the Argives to make themselves masters of Epidaurus, which was, however, defeated by the Lacedæmonians throwing a strong garrison into the place.

Renewal of the war.

The next being the fourteenth year of the Peloponnesian war, a Spartan army, under the command of Agis, entered the territory of Argos; but just as battle was on the eve of commencing, a truce was suddenly concluded between two of the Argive generals and the king of Sparta. But it so happened that neither party felt satisfied with this proceeding, and both the king and the generals were very ill received by their respective fellow-citizens. Accordingly, on the arrival of some fresh troops from Athens, the Argives immediately broke the truce; and a battle ensuing soon afterwards, the allied army was defeated with great slaughter by Agis, who thus achieved a victory on the very spot which was afterwards destined to acquire additional celebrity as the scene of one of the most disastrous defeats which the Spartan arms ever experienced. In the winter a strong party in Argos joined the Lacedæmonians; in consequence of which that city renounced her alliance with Athens, and concluded peace with Sparta for the period of half a century. Further, in compliment to their new allies, the Argives abolished democracy in their city, substituting an aristocracy in its stead; and also assisted the Lacedæmonians in forcing the Sicyonians to adopt a similar form of government. Notwithstanding all this, however, the Argives, with a levity natural to the Greeks, renounced their

[1] Thucydides, iv. 39.

[2] Alcibiades seems to have already begun to take part in public affairs. See a passage in the Wasps of Aristophanes, 44, where his manner of speaking is ridiculed. At this time he was about twenty-four years of age.

[3] Thucydides, v. 18, 19, 20.

alliance with Sparta the following year; abolished aristocracy, drove the Lacedæmonians out of the city, and renewed their league with Athens. On the other hand the Athenians, convinced of the bad faith of Perdiccas, king of Macedonia, abjured his alliance and declared war against him; preferring, as they said, an open enemy to a treacherous friend. And as Argos was still distracted by adverse factions, Alcibiades in the course of the ensuing year terminated all disputes between them by the expulsion of the Spartan party. He then sailed for the island of Melos, which had shown the greatest inveteracy against his countrymen, in order to punish the inhabitants for repeated acts of wanton hostility; but perceiving that the reduction of the island would be a work of time, he left a considerable body of forces there, and returned to Athens. In his absence, however, the capital of Melos surrendered at discretion, and the inhabitants were treated with the utmost severity; all the men capable of bearing arms being slaughtered, and the women and children carried into captivity.

Loss of the Athenian army in Sicily.

In the beginning of the seventeenth year, Nicias was appointed commander-in-chief of an expedition destined to act against the Syracusans, with Alcibiades and Lamachus as colleagues. But whilst the necessary preparations were being made, Athens was thrown into terrible confusion by the defacing of the Hermæ or statues of Hermes, of which there was a great number in the city; an outrage equally wanton in itself, and appalling to the people of Athens, who revered these statues both as monuments of art and as symbols of religion. Great efforts were in consequence made to discover the perpetrators of this sacrilege; but although ample rewards were offered, no disclosure was then made. At last, from some cause unexplained, suspicion fell upon Alcibiades, who in consequence received orders to return immediately from Sicily in order to take his trial for this alleged crime. But he knew the temper of his countrymen too well to trust himself to their mercy; and, instead of returning to Athens, he fled to Sparta, where he met with a gracious reception; whilst the Athenians were severely punished by the loss of their army, generals, and fleet, in Sicily; a disaster which the superior abilities of Alcibiades would in all probability have prevented.

Intrigues of Alcibiades.

The nineteenth and twentieth years of the war were spent by the Athenians in equipping a new fleet in order to repair their losses; but Alcibiades hurt their interests greatly by persuading Tissaphernes the Persian to league with the Spartans against them, and at the same time stirring up several of the Ionian states to revolt against what he described as the mob government of Athens. Equally restless and profligate, however, this celebrated Athenian had scarcely established himself amongst his new allies when he contrived, by means of a handsome person and an insinuating address, to debauch the wife of Agis the Lacedæmonian commander; and as the latter strongly resented the affront which had been put upon him, the Athenian seducer was obliged to quit Sparta and pass over into Persia. Here, however, he met with a favourable reception from Tissaphernes, who profited much by his advice, which, in fact, was equally shrewd and insidious. "Let the Greeks," said he to the Persian general, "exhaust themselves by their mutual wars; foment discord among them, which you will always find comparatively an easy task; take care never to let one state be totally destroyed, but always to support the weaker party against the more powerful;—follow this policy for a time, and the Greeks will themselves spare you the trouble of conquering them. By their incessant contests they will so weaken themselves that their country will become the prey of the first invader."

Abolition of democracy.

As may easily be supposed, Tissaphernes readily acquiesced in these counsels; upon which Alcibiades wrote privately to some of the officers in the Athenian army at Samos, informing them that he had been treating with the Persians in behalf of his countrymen, but that he did not choose to return till the democracy should be abolished; adding, that the Persian king disliked a democracy, but would immediately assist them if that was abolished, and an oligarchy established in its stead. On the arrival of Pisander and other deputies from the army with the proposals of Alcibiades, the oligarchial party succeeded in overturning the democratic constitution; in consequence of which Pisander and the deputies received directions to return to Alcibiades, in order to ascertain precisely on what terms the king of Persia was disposed to enter into an alliance with them. But perceiving that Tissaphernes was by no means inclined to assist the Athenians, on account of their recent successes, Alcibiades artfully set up such extravagant demands in the king of Persia's name, that the Athenians of themselves broke off the treaty, and thus enabled him to outwit both parties without offending either. But notwithstanding the failure of the negotiations with Tissaphernes, the democratical form of government was abolished, first in the cities subject to Athens, and afterwards in the capital itself; whilst, according to the scheme substituted in its stead, it was provided that the old form of government should be entirely dissolved;—that five Prytanes should be elected;—that these five should choose a hundred others, and each of the hundred choose three more;—that the Four Hundred thus elected should become a senate with full power, but should nevertheless consult occasionally with Five Thousand of the wealthiest citizens, who alone were henceforth to be accounted The People;—and that no authority whatever should remain in the hands of the lower class of citizens. Such was the scheme proposed by Pisander; and although the people were opposed to this change, those who conducted it, being men of great parts, found means to establish it by one of those unceremonious acts of audacity which commonly distinguish revolutions in popular governments.

The army declares for a democracy.

In the meanwhile the Athenian army having changed their mind, declared for a democracy; and recalling Alcibiades, they invested him with full power, and insisted on his immediate return to Athens for the purpose of restoring the ancient government. But he peremptorily refused to comply with their wishes; persuaded them to stay where they were in order to save Ionia; and further prevailed on them to allow some deputies, who had been sent by the new governors of Athens, to deliver the message with which they were charged. When the deputies had done so, Alcibiades enjoined them in reply to return immediately to Athens, and acquaint the Four Hundred that they were commanded instantly to resign their authority and restore the senate; adding, that the Five Thousand might retain their power for the present, provided they used it with moderation. By this answer the city was thrown into the utmost confusion; but the party of the new government prevailing, ambassadors were despatched to Sparta with orders to conclude peace upon any terms. This, however, was not so easy a matter as some had hastily imagined; for the Spartans proved intractable; and Phrynichus, the chief of the embassy, was murdered on his return. When the news of his death arrived, Theramenes, the head of the democratical party, seized the leaders of the Four Hundred; upon which a tumult ensued that had almost proved fatal to the city itself; but the people being at last dispersed, the Four Hundred immediately assembled, and sent deputies to the people, promising to comply with all their reasonable demands. A day was accordingly appointed for convoking a general assembly, and settling the form of government; but when it arrived, intelligence was brought that the Lacedæmonian fleet was in sight, and steering directly for Salamis. Thus all was again thrown into confusion; and the people, instead of deliberating on the subject proposed, ran in crowds down to the port, whence a fleet of 36 ships was immediately despatched, under the command of Timochares, to engage the

enemy, who were perceived to be making for Eubœa. But this fleet was utterly defeated, 22 ships being taken, and the remainder either sunk or disabled; and this disaster was followed by the revolt of all Eubœa, except the small district of Oreus. When the dismal tidings reached Athens, everything was given up for lost; and had the Lacedæmonians taken this opportunity of attacking the city, they would undoubtedly have succeeded in the attempt, and thus put an end to the war by the subjugation of Athens. But being at all times slow, especially in naval affairs, they allowed the Athenians time to equip another fleet, and to retrieve their affairs; while Alcibiades, by his intrigues, so effectually embroiled the Persians and Peloponnesians that neither party knew whom to trust, and mutual distrust at length rose to such a pitch as almost to involve them in open hostility; and several advantages gained by the Athenians at sea tended to revive their hopes and restore their confidence.

Alcibiades triumphant and disgraced.

During the succeeding years of this celebrated war the Athenians were also in the first instance very successful. Thrasybulus obtained a signal advantage at sea; and in the same day Alcibiades gained two victories, one by land and another by sea, capturing the whole Peloponnesian fleet, besides an immense spoil. The Spartans, humbled by these reverses, were reduced in their turn to the necessity of suing for peace. But the Athenians, intoxicated with success, sent back the envoys without vouchsafing an answer to their proposals; and the Spartans, justly incensed at this insolent and contemptuous conduct, renewed the war with the utmost vigour, and soon after made themselves masters of Pylos. Nor was this the only misfortune of the Athenians. The Megarians surprised Nisæa, and put the garrison to death; an act which so exasperated the Athenians, that they immediately sent an army against that people,—defeated them with great slaughter,—and committed horrid devastations, in revenge for the affair of Nisæa. But these misfortunes were still in some measure counterbalanced by the great actions of Alcibiades, Thrasybulus, and Theramenes. When Alcibiades returned in triumph to Athens, 408 B.C., he brought with him a fleet of 200 ships, together with such a load of spoils as had never been seen in the capital since the conclusion of the Persian war. The people crowded to the port to behold the hero as he landed; old and young blessed him as he passed; and next day, when he had delivered a harangue to the assembly, they directed the record of his banishment to be thrown into the sea, absolved him from the curses he lay under on account of the alleged sacrilege, and created him generalissimo of their forces. But this enthusiasm was too violent to be lasting; and in point of fact a casual reverse which Alcibiades sustained soon after this obliterated all remembrance of his former services, and involved him in disgrace. Having sailed to the Hellespont with part of his fleet, he left the remainder under the command of Antiochus his pilot, with strict orders to attempt nothing in his absence. But the pilot chose to disobey his instructions, and having provoked Lysander, the Lacedæmonian admiral, to an engagement, he paid for his temerity by a total defeat, with the loss of fifteen ships, and that of his own life into the bargain. On receiving intelligence of this disaster, Alcibiades returned, and endeavoured to induce the Lacedæmonian commander to hazard a second battle; but Lysander was too prudent to incur such a risk; and in the meanwhile the Athenians deprived Alcibiades of his command, and named ten new generals in his stead. By this proceeding their ruin was sealed. Conon, who succeeded to the command, was beaten by Callicratidas, Lysander's successor; but being afterwards strongly reinforced, he retrieved this disgrace by defeating the Lacedæmonians with the loss of no less than 77 ships. Such a victory might have been supposed to inspire the Athenians with some gratitude towards the generals who had gained it; but instead of this eight of them were recalled, on pretence of their not having assisted the wounded during the engagement: two were prudent enough not to return; and the six who trusted to the justice of their country were all put to death without mercy.

Athenians defeated at Ægospotami.

The following year Lysander, appointed commander of the Peloponnesian fleet, succeeded in capturing both Thasus and Lampsacus. Conon was immediately despatched against him with 180 ships; a force so superior to that under Lysander, that the Lacedæmonian declined accepting battle, and was consequently blocked up in the river Ægos. While the Athenians lay there observing him, they grew quite idle and careless, insomuch that Alcibiades, who had built a habitation for himself in the neighbourhood, entreated them to be more watchful, as he well knew Lysander's great abilities, and dreaded that they might have reason to repent their security if they disregarded his advice. They replied by expressing their wonder at the assurance of one who was an exile and a vagabond, in pretending to offer advice to them; adding, that if he gave them any further trouble, they would seize and send him a prisoner to Athens. The consequences of such conduct may easily be imagined. Lysander fell unexpectedly upon them, and gained a complete victory; Conon, with only nine galleys, escaping to Evagoras at Cyprus: after which the Lacedæmonian commander returned to Lampsacus, where he put to death Philocles with 3000 of his soldiers, and the whole of the officers except Adimantus. He then reduced all the cities subject to Athens, and artfully sent home their garrisons, that the city, overstocked with inhabitants, might thus be rendered incapable of holding out for any length of time when he came to besiege it.

Capture of Athens.

Nor was any time lost in undertaking this decisive operation. Lysander appeared before the harbours with a fleet; while Agis, at the head of a powerful army, invested it on the land side. For a considerable time the Athenians resisted both attacks; but they were at last forced to send deputies to Agis, who referred them to Sparta; and when they repaired thither they were told that no terms could be granted unless they consented to demolish their walls. They next applied to Lysander, but he also referred them to Sparta; to which Theramenes, with other deputies, was immediately despatched. On their arrival they found assembled the council of the confederates, who all except the Spartans gave their votes for the utter destruction of Athens; but the latter would on no account consent to the ruin of a city which had deserved so well of Greece. The Athenian envoys did all in their power to mitigate the severity of the terms, but without effect; and finally peace was concluded, on condition that the long walls and the fortifications of the port should be demolished, and that the Athenians should deliver up all their ships excepting twelve, receive back such as had been banished for political offences, and consent to follow the fortune of the Lacedæmonians. And these severe terms were punctually executed. Lysander caused the walls and fortifications to be pulled down; established an oligarchy expressly against the will of the people; and thus completed the ruin of Athens in the twenty-seventh year of the Peloponnesian war, and the 404th B.C.

The Thirty Tyrants.

As soon as the Lacedæmonian had demolished the long walls and the fortifications of the Peiræus, he constituted a council of thirty, with power, as was pretended, to make laws, but in truth to subjugate the state. These were the persons so famous in history under the title of The Thirty Tyrants. They were all the creatures of Lysander; and as they derived their power from conquest and the law of the sword, they exercised it in a manner worthy of its origin. Instead of making laws, they governed without them; they appointed a senate and magistrates at their will; and, lastly, they applied for a garrison from Lacedæmon, that, under the protection of a foreign military force, they might give a freer and bolder scope to the licentiousness of tyranny.

Attica.

Critias and Theramenes, two men of the greatest power and abilities in Athens, were at the head of this odious oligarchy. The former was ambitious and cruel beyond measure; but the latter was of a more merciful and humane disposition. The one pushed on all the bloody schemes framed by his confederates, and carried into execution many of his own; the other always opposed them, at first with moderation, at last with vehemence. In the course of his expostulations he said, that power was given them to rule and not to despoil the commonwealth; that it became them to act like shepherds, not like wolves; and that they ought to beware of rendering themselves at once odious and ridiculous, by attempting to domineer over all, being a mere handful of men, whom the slightest resistance would crush. This hint was not thrown away; for the remaining oligarchs immediately chose three thousand persons, whom they constituted the representatives of the people, and on whom they granted the notable privilege of not being liable to be put to death except by judgment of the senate; thereby assuming by implication a power of sacrificing the other Athenian citizens at their pleasure. Nor were they slow in practically confirming the justice of this interpretation; for as many as they conjectured to be unfriendly to the government in general, or to any of themselves in particular, they put to death, without cause and without mercy. Theramenes stoutly resisted this wantonness of cruelty; and absolutely refusing to concur in such measures, Critias accused him to the senate as a man of unsteady principles, sometimes for the people, sometimes against them, and favourable to nothing except innovation and revolution. The accused admitted that he had sometimes changed his measures, but alleged that he had always done so for the benefit of the people. It was solely with this view that he made peace with Sparta, and accepted of office as one of the Thirty; nor had he ever opposed their measures while they cut off the wicked; but when they began to destroy men of fortune and family, solely for the purpose of confiscating their property, then he owned he had differed with them, which he conceived to be no crime against the state.

Critias and Theramenes.

Theramenes put to death.

Whilst Theramenes was speaking, Critias, perceiving the impression made upon the senate by his words, withdrew abruptly; but he soon returned with a guard, crying out that he had struck the name of Theramenes out of the list of the three thousand; that the senate had therefore no longer cognizance of the cause; and that the Thirty had already judged and condemned him to death. Theramenes, seeing that they intended to seize him, fled to the altar in the midst of the senate-house, and laying his hands thereon, said, "I do not seek refuge here because I expect to escape death, or desire it; but that, tearing me from the altar, the impious authors of my murder may interest the gods in bringing them to speedy judgment, and thereby restore freedom to my country." The guards then dragged him from the altar, and carrying him to the place of execution, he drank the poison with undaunted courage; reminding the people, with his last breath, that the same tyrants who had arbitrarily struck his name out of the list of the three thousand, might also strike out any of theirs, and that none could say whose turn it might next be to drink the fatal cup which he had just drained. The death of this heroic man was followed by a train of murders such as are to be found recorded only in the annals of republican oligarchies or aristocratical republics. Almost every citizen of any eminence either died a violent death or was driven into exile.[1]

At length Thrasybulus, and such as like him had taken shelter in the Theban territory, resolved to hazard every thing rather than remain in a state of perpetual exile from their country; and although he had no more than thirty men on whom he could depend, yet, inspired by the remembrance of the victories he had heretofore obtained in the cause of his country, he boldly made an irruption into Attica, and seizing on Phyle, a castle at a short distance from Athens, numbers flocked to his standard, and he soon found himself at the head of seven hundred men, maddened by cruelty and oppression, and prepared to devote themselves for their country. The tyrants of course had the disposal of the Spartan garrison, which they employed to reduce Thrasybulus and his party; yet he prevailed in various skirmishes, and at last obliged them to decamp from Phyle, which they had intended to blockade. The Thirty and their partisans conceiving it expedient to obtain possession of Eleusis, marched thither; and having persuaded the people to go unarmed out of their city, on the pretence of numbering them, the monsters instantly commenced an indiscriminate massacre. But the forces of Thrasybulus increasing daily, he seized on the Peiræus, which he fortified in the best manner he could; and although the tyrants came down against him with the utmost force they could raise, he defended himself with so much obstinacy, that in the end they were forced to retreat, having lost before the place not only a great number of their men, but Critias, the president of the Thirty, and other members of this sanguinary oligarchy. By this gallant resistance the fate of the oligarchy was sealed. The people indeed differed among themselves; and the sanguinary monsters, who during their short administration had destroyed more men than had fallen during half the Peloponnesian war, had still a considerable party in Athens. But happily the cause of humanity prevailed; the tyrants were expelled, and withdrew to Eleusis.

Attica.

Tyranny overthrown.

But although the citizens had changed the government, they had made no agreement with those in the Peiræus;[2] whilst the tyrants, who had retired to Eleusis, sent deputies to Lacedæmon to announce the revolt of the Athenians, and request assistance to reduce them. Nor did their application prove fruitless. Besides remitting them a large sum of money to aid their intrigues, the Lacedæmonians appointed Lysander commander-in-chief, and his brother admiral; resolving to send both a fleet and an army, in order to reduce Athens a second time, and, as most of the Greek states then strongly suspected, to add it to their other dominions. Nor is it improbable that this design would have taken effect, had not Pausanias, the rival and enemy of Lysander, resolved to obstruct it by every means in his power. With this view he caused another army to be raised, of which he took the command, and immediately marched for the ostensible purpose of besieging the Peiræus. But while he lay before the place, and pretended to attack it, he entered into a private correspondence with Thrasybulus, instructing him what propositions to make in order to induce the Lacedæmonians, who were suspected by their allies, to abandon the contest, and conclude a peace upon equitable terms. These intrigues had all the success that could be desired. The Ephori who were with Pausanias in the camp concurred in his measures; and in a short time a treaty was concluded, by which, amongst other things, it was provided that all the citizens of Athens should be restored to their homes and privileges, with the exception of the Thirty, the Eleven who had acted as their ministers, and the Ten who during the time of the oligarchy had been constituted governors of the Peiræus; that all should remain quiet for the future in

Spartans attempt to reduce Athens a second time.

[1] Alcibiades died during the tyranny of the Thirty. He was then in the forty-fourth year of his age, and had been more or less engaged in public affairs for about twenty years. He was a bold and able, but bad man; of great personal and mental endowments, but utterly devoid of principle, and addicted to the most shameless profligacy; prompt, skilful, brave, enterprising, restless, ambitious, yet fond of intrigue and finesse in all things; an enemy to liberty, under the mask of ultra-democracy; and reckless of every consideration which was opposed to the gratification of his pride, vanity, ambition, sensuality, revenge, and love of perpetual bustle and turmoil.

[2] Οἱ ἐν Πειραιεῖ, that is, Thrasybulus and his party.

the city; and that, if any persons were afraid to trust to this agreement, they should have permission to retire unmolested to Eleusis. Pausanias then marched away with the Spartan army; and Thrasybulus at the head of his forces entered Athens, where, having laid down their arms, they sacrificed with the rest of their fellow-citizens in the temple of Athena, and then, to the great delight of all, restored the popular form of government, which was afterwards consolidated by an act of general amnesty and oblivion.[1]

Virtue of Thrasybulus.

Throughout the whole of this transaction the conduct of Thrasybulus was admirable. When he first seized the castle of Phyle, the tyrants privately offered to receive him into their number instead of Theramenes, and to pardon at his request any twelve persons whom he might choose to name. But he nobly replied that he considered his exile far more honourable than any authority could be, purchased on such terms; and by persisting in his design he accomplished the deliverance of his country from a ferocious and sanguinary oligarchy which, as Isocrates informs us, had put 1400 citizens to death without any form of law, and had driven 5000 more into banishment, besides committing a variety of other acts of cruelty and oppression.

But, although Athens was thus restored to liberty by the virtuous patriotism of Thrasybulus, the age of Athenian glory had passed away. From this period till the reign of Philip of Macedonia the republic gradually sunk in energy, though it still continued to enjoy tolerable prosperity; and although many of the great masterpieces of Athenian genius were the productions of a later age, the most splendid of these only serve to prove beyond all question that the national spirit had degenerated, and that, "sunk in its glory, decayed in its worth," the Athenian Demos, which had once been the wonder and terror of the world, was now prepared to receive the law from the hands of almost any master. Philip accordingly found but little difficulty in extinguishing the feeble remains of liberty; and his son Alexander having completed the subjugation of Greece, the history of the Grecian states henceforward ceases to be of almost any interest. With regard to the capital, however, a rapid sketch of its history from this period till the present time will be found under the article ATHENS, to which reference is accordingly made.

Having thus laid before the reader an outline of the general history of Attica, it now only remains to give, as briefly as possible, some account of the character, government, religion, and public economy of the Athenians.

Character of the Athenians.

National character may be defined as the aggregate of those qualities or peculiarities, physical, moral, and political, by which one community of men is distinguished from another; in other words, it is a complex result produced by the action and re-action of primary and secondary causes, or the joint effect of all the circumstances, original and accidental, in which a people happens to be placed. But these causes are so various, both in kind and degree,—the operation of one is so much affected and modified by that of another, and direct physical becomes so much blended with indirect moral and political influences,—that, whilst it is comparatively an easy matter to determine in what respects the general characters of nations differ, it is exceedingly difficult, not to say impossible, to resolve that of any one into its constituent elements, and to assign to each its due share in the production of the ultimate result. The instrument of analysis which, employed in the investigation of physical laws, has led to the discovery of the most sublime truths, and extended the knowledge and consequently the power of man over the material world, is applicable only in a very limited degree even to the most complex phenomena of mind. Here we possess no manner of control over the subject of our inquiries; we have no power of placing it in new situations, of trying it by a variety of tests, or of submitting it to a course of skilfully contrived experiments. All that we can possibly do is either carefully to watch its manifestations, where these fall under our own notice, or to apply the principles of a sound logic to such observations as have been recorded by others, and thus to endeavour to make the nearest approximation we can to the truth. In such a method of investigation, however, the liability to error must necessarily be great; for, independently of its own obvious imperfection, the subtile nature of the phenomena observed, and the constant transitions and modifications they experience, produce continual mistakes upon the part of the observer; whilst the spirit of system or of theory, which is generally most active where our knowledge is least accurate and extensive, instead of facilitating the correction of such mistakes, contributes rather to render them inveterate, and thus opposes a serious obstacle to the progress of sound inquiry. In attempting to form a judgment of the national character of a people, therefore, it becomes us to be equally on our guard against dogmatism in the statement of facts, and rash generalization in the inferences deduced from them. The former, indeed, are but too frequently stated without the qualifications proper to be applied to them; the latter is almost certain to lead into error and mystification. In cases where physical and moral causes are blended together in their operation; where primary results experience endless modifications from the influence of circumstances and the re-active working of positive institutions; and where we are in possession of no instrument of analysis by which the complex whole can be reduced into its constituent parts or elements; it is manifest that no theory which human ingenuity can invent will ever be sufficient to explain all the phenomena of national character, or to account for the varied and often incongruous phases which it assumes. Some writers, for instance, have amused themselves with referring to the influence of climate all the varieties observable in the characters and institutions of different nations; whilst others, again, have ascribed to the joint effect of moral and political causes, operating under peculiar circumstances, the diversities in question. But it must be obvious, on the slightest consideration, that both these theories are equally untenable, inasmuch as national character is not the result of one cause or set of causes, but of all the causes and influences, of whatever kind, which act, either directly or indirectly, upon the general mind of a people. Instead of attempting to generalize, therefore, where generalization is from the very nature of things inadmissible, let us endeavour simply to point out some of the leading features in the character of that illustrious nation which in ancient times inhabited the territory of Attica, and filled the world with the renown of their achievements both in arts and in arms.

The Athenians surpassed all the other Greeks in physical conformation no less than in mental endowments. Among this people, indeed, strength and symmetry of body were happily united with many of the rarest attributes of mind. For these advantages they were indebted partly to nature, and partly to a system of education, which, apparently limited and imperfect, was nevertheless singularly calculated to develop their peculiar capabilities. Habitual exercise may not be capable of creating beauty of form originally, but it certainly tends greatly to improve it; and in the human frame elegance and grace are seldom divorced from the free and flexible vigour acquired in the palæstra. A similar observation may be applied to the human mind. Admitting that certain tribes or races of men are, taken as a whole, gifted by nature with finer faculties, nicer perceptions, and more acute sensibilities, than others, no one can doubt that these may be prodigiously improved by education; which, in fact, is to the mind what the chisel of the sculptor is to the rude block of marble,—that which fashions it, by scarcely per-

[1] This war lasted ten months. (Xenophon, *Hist. Græc.*, ii. 4, 43.)

ceptible degrees, into the fairest proportions, and gives animation and expression to that which was originally a rude and inert block. The Athenians were early sensible of this important truth; and although, till the age of Pericles, the three principal preceptors of their youth were the grammarian, the teacher of music, and the master of the gymnasium, yet even this limited circle of instructors was not ill adapted to call forth and keep in exercise the peculiar faculties for which they were so remarkably distinguished, and to prepare them for a more extended range of instruction. To the study of music, indeed, they were enthusiastically devoted, because in that delightful art they found a natural scope for the gratification of those nice and delicate perceptions which constituted a prominent characteristic of their minds;[1] nor will its union with the study of grammar be deemed surprising, when we reflect that it was probably this circumstance, aided by an organic and intellectual sensibility altogether unrivalled, "which gave form to the most harmonious language ever spoken among men, and guided invention to the structure of that verse which, even under the gross disguise of modern pronunciation, is still universally charming."[2] But there were other elements in the Athenian character besides a love of music, poetry, and the fine arts, which both nature and education had contributed to form.

Speaking of this people, Plutarch, after describing them as at once passionate and placable, prone to anger, yet easily appeased, goes on to observe, that their minds were not formed for laborious researches; and that, although they seized a subject as it were by intuition, yet they wanted the patience and perseverance requisite for a thorough examination of its various bearings and ramifications. An observation more superficial in itself, and arguing a greater ignorance of the real character of the Athenians, cannot easily be imagined. That they were remarkable for ardour and vivacity of temperament, quickness of sensibility as well as of apprehension, and versatility of feeling as well as of genius, has not been disputed. But there is nothing in all this which necessarily presupposes or implies an incapacity for the prosecution of subjects requiring patient thought and persevering attention. The French, in point of national character, hold nearly the same relative place among the modern nations of Europe that the Athenians held among the states of ancient Greece; yet it is matter of notoriety, that in the cultivation of the natural and the exact sciences, that is, in the prosecution of those subjects where patience and perseverance are pre-eminently indispensable, they have for a considerable time outstripped all competition, and borne the palm alone. This was precisely the case with the Athenians. A love of profound research and curious speculation seems to have been as inherent in their character, and as congenial to their national temperament, as a love of poetry, music, and the fine arts.

Love of speculative inquiries.

The fire which Thales lighted up was never afterwards wholly extinguished amongst the Greeks. He had kindled his torch at the altar of science in Egypt, and it burned brightly in the propitious atmosphere to which it was transferred by the father of Greek philosophy. The Ionian school, of which this philosopher became the founder, was followed in quick succession by the Italian and Eleatic, where the physical and metaphysical sciences were cultivated with equal success; and in the dialogues of Plato, ample evidence may be found of the zeal and ardour with which the laws both of mind and of matter were investigated in Athens, as soon as the violence of political contention had subsided, and a respite from wars and revolutions gave leisure for the discussion of such subjects. God, the Universe, and Man, at once divided and engrossed the whole of their attention. The question first asked was, What is God? and to this various and discordant answers were of course necessarily given. According to Thales, he is the most ancient of all things, for he is without beginning; he is air, said Anaximenes; he is a pure mind, quoth Anaxagoras; he is both air and mind, contended Archelaus. Democritus thought him mind in a spherical form; Pythagoras, a monad, and the principle of good; Heracleitus, an eternal circular fire; Parmenides, the finite and immovable principle, in a spherical form; Melissus and Zeno, one and everything, the only eternal and infinite. But these answers, being all more or less physical, did not satisfy the question; a vacuity was still left; and Necessity, Fate, and Fortune or Accident, were the principles called in to fill it up. The Universe gave rise to another set of disputations. According to some, what is has ever been, and the world is eternal. Others, again, argued that the world is not eternal, but that matter is eternal. And here a multitude of questions arose. Was this matter susceptible of forms, of one or of many? Was it water, or air, or fire, or an assemblage of corpuscular atoms, or an infinite number of indestructible elements? Had it subsisted without movement in the void, or had it an irregular movement? Did the world appear by intelligence communicating its action to it, or did the Deity ordain it by penetrating it with a part of his essence? Did these atoms move in the void, and was the universe the result of their fortuitous concourse? Are there but two elements in nature, earth and fire; and by these are all things produced? or are there four elements, whose parts are united by attraction and separated by repulsion? In a word, "causes and essences; bodies, forms, and colours; production and dissolution; the great phenomena of visible nature—the magnitudes, figures, eclipses, and phases, of the two heavenly luminaries; the nature and division of the sky; the magnitude and situation of the earth; the sea, with its ebbs and flows; the causes of thunder, lightning, winds and earthquakes;—all these furnished disquisitions which were pursued with an eagerness of research and intenseness of application peculiar to the Greeks."[3] Nor did Man form a subject of less interesting and curious speculation than the universe of which he was considered an epitome. All allowed him a soul and an intelligence, but all differed widely in their ideas respecting this soul or intelligence. Some maintained that it was always in motion, and that it moved by itself; others thought it a number in motion; some considered it the harmony of the four elements; others, again, variously represented it as water, fire, blood, a fiery mixture of things perceptible by the intellect, which have globose shapes and the force of fire, a flame emanating from the sun, an assemblage of fiery and spherical atoms, like those subtile particles of matter which are seen floating in the rays of the sun.

Such were a few of the speculations which science had devised for employing the thoughts of the active-minded men in Greece, particularly in Attica; and when to these we add the ethical and political systems of the Academy, the Lyceum, the Porch, and the Gardens, to say nothing of that of the New Academy founded by Arcesilaus, and ably maintained by Carneades, or of the attention paid by almost all the philosophers to the cultivation of pure geometry, some idea may be formed of the extent of Plutarch's misrepresentation of the Athenian mind when he described

[1] What the music of the ancients ever was, we have now little means of judging, as none of it has been transmitted intelligibly to us; but that the Grecian music, even from the earliest times, had extraordinary merit, we have Plato's testimony in very remarkable words (*Minos*, 46; *Convivium*, 333); and Aristotle (*Polit.* l. viii. c. 5) coincides in judgment with his great master. (Mitchell's *Aristophanes*, prel. disc. p. xxxv. xxxvi.)

[2] Mitchell's *Aristophanes*, prel. disc. *ubi supra*.

[3] *Ibid.* p. xli. *et seqq.*

it as incapable of pursuing laborious researches, and as wanting in persevering and continuous attention. The very reverse of this, as has just been shown, was the truth; and, independently of the exemplification of a similar capacity for deep and laborious researches on the part of a modern nation whose character in many particulars resembles that of the ancient Athenians, it is no more than a sound view of the principles of human nature might, anterior to all experience, have led us to anticipate. For, as travellers often reach the same destination by different routes, so men frequently pursue the same course from different motives or impulses. In the prosecution of scientific investigations, for instance, the Frenchman and the German are each persevering and laborious; but the former is impelled by an ardent curiosity and an overmastering ambition which concentrate the whole energies of his mind on the subject which has powerfully attracted his attention, and merge all his feelings and desires in the attainment of one great object. The latter, without enthusiasm, perhaps with no definite object of ambition in view, pursues a similar career, because it belongs to his nature to persevere in whatever he may have undertaken or commenced. The principles by which these inquirers are are set in motion are different, and the rates of advancement consequently unequal; but diligent and persevering labour is nevertheless alike predicable of each. The one travels, so to speak, in a light chariot, and compasses the distance to be travelled over at an accelerated pace; the other trundles it slowly along in a heavy lumbering post-waggon, but in time he also reaches the same destination. This analogy will probably serve to bring out the distinction here pointed at, and which, indeed, it is necessary to keep steadily in view, in order to form a just conception of the Athenian character. The native of Attica may be considered the Frenchman of Greece; quick, lively, sensitive, versatile, inconstant, full of that mercurial spirit which shows itself equally in extreme delicacy of organic perception, and intuitive rapidity of mental apprehension; yet endued with an ardent and unquenchable curiosity, together with an inherent taste for subtile and abstract speculations, under the joint influence of which he was capable of penetrating the most recondite mysteries of science. Much of the excellence attainable in art is doubtless due to superiority of physical constitution and of natural character; but in science, although original genius will always assert its pre-eminence, and distinguish itself by the felicity of its intuitions, unremitting labour is the *conditio sine qua non* of great and signal success; and it is not a little remarkable to find this condition so strikingly exemplified in the character of a people whose more obvious qualities would seem incompatible with steady concentration of thought, and whom a superficial observer has accordingly pronounced incapable of that intense, resolute application, which, in fact, constituted one of their most distinguishing national peculiarities.

Effects of political institutions.

Politically considered, the Athenian character took by reflection the hue of those republican institutions to which it had originally given birth; and this, blending and intermingling with its natural lights and shadows, produced a composite mass, which moral analysis unfortunately has no prismatic power of resolving into its primary elements. Love of liberty, however, as liberty was then understood, formed the ruling principle as well as passion of the people. An equality of political rights, or, in other words, an equal right in all free citizens to aspire to the exercise of political power, constituted the essence of the Athenian form of government. Civil liberty, the benign discovery of modern times, was then unknown, or at least unenjoyed. Political equality was the only species of liberty understood or enjoyed in the ancient republics, and in those of Italy during the middle ages. It was this which had such powerful charms for the citizens of those democracies; it was this of which they were so passionately enamoured; it was this which gave so effective a stimulus to all the faculties of the human mind, and produced those wonders of genius and of art which have exhausted the admiration, and rendered hopeless the rivalry, of succeeding times. The glory of the country in fact formed the glory of every citizen belonging to it; and he felt himself directly participant in all that contributed in any way towards its greatness or renown. For a short time, indeed, an oligarchical usurpation might oppress the people, or the ambition of a fortunate soldier or crafty statesman might prove dangerous to liberty; but a sudden popular explosion might overturn the one, and the ostracism expel the other. The re-action of such a political system upon the national character could not fail to be powerfully marked. Its immediate products were extreme jealousy of those intrusted with power, and an incessant watchfulness over all their proceedings; an intense, passionate detestation of tyrants and tyranny; an ardent and active zeal in defence of public liberty when assailed, whether from within or from without. Factious turbulence, inconstancy, and love of change, may also be numbered amongst the effects of a system of government purely democratical; and, paradoxical as it may seem, these for a time constitute its best if not its only safeguards. Much has been said and written about republican ingratitude, which, indeed, has long been proverbial; but those who declaim on this theme do not reflect, that while the vice in question is not the peculiar reproach of democracy, the essence of that form of government consists in anxiously guarding against the aggrandizement of individuals or classes, and in crushing every aspirant who attempts to raise his head above the common level. Republics have often had occasion to regret their rewards, seldom their punishments.

General results.

If we are not greatly mistaken, these observations furnish a key to the right intelligence of the Athenian character, the leading features of which were unquestionably moulded and fashioned by their political institutions. They were fickle, versatile, liable to sudden gusts of passion, but easily appeased; inconstant in their affections, but not implacable in their hatreds; jealous, factious, turbulent, impatient of command, and prone to resent the assumption of superiority; attentive to the information and instruction afforded them by eminent citizens, yet intolerant of dictation, and, in their best days, ready to repress an overgrown and dangerous reputation; fond of flattery, and too apt to lend a delighted ear to the adulation of sycophants or demagogues, but not insensible to virtue, nor unwilling to listen to those honest patriots who proved their sincerity by courageously exposing the vices and follies of their countrymen; brave in the field, and liable to be excessively elated with victory or depressed with misfortunes, but seldom chargeable with dishonouring success by inhumanity to the vanquished, or deepening the disgrace of defeat by humiliating or abject concessions to the victor; generous in their sentiments; bold and free in their opinions; invariable in their sympathy with and admiration of genius; constant in their love of liberty and their country; and never backward to repair the errors or injustice committed under the influence of pernicious advice, passionate excitement, or the headlong impetuosity of an ardent and uncontrollable temperament. In their private conduct they were courteous, mild, humane, polished, liberal, and enlightened; simple in their manners, frugal in their habits, and but little addicted to any kind of ostentation or parade, even after their victories had brought them in contact with oriental luxury, and when their riches enabled them to rival in costliness and in splendour the nations whom they conquered. All their sumptuousness and magnificence was reserved for and lavished on those public edifices and monuments of art which made Athens the pride of Greece, the envy of the surrounding nations, and the admiration of the world at large. Such was the Athenian Demos in the days of its glory and independence, when, by the mouth of Aristides, it declared to the ambas-

sadors of the Great King, "that it was impossible for all the gold in the world to tempt the republic of Athens, or to prevail with it to sell its liberty and that of Greece," and when public virtue maintained the purity and vigour of public institutions.

Government.

During the period which elapsed from the abolition of royalty till the appearance of Solon in the character of a lawgiver and codificator, the constitution of the Athenian government experienced frequent mutations. To the kings succeeded the hereditary archons, who held their office for life, and were in fact sovereigns under another designation. Of this the nobles grew at length tired; and, accordingly, on the death of Alcmæon (B.C. 752), Charops was raised to the archonship upon the condition of holding it for ten years only. He was followed in succession by six others, who exercised the functions of the office under the same decennial limitation. But on the expiration of the archonship of Eryxias, a further and greater change took place, in 682 B.C. The duration of the office was then limited to a single year, and its duties were divided amongst nine persons, chosen out of the first order of the state, the eupatrids or nobles only. These functionaries all bore the title of archon, but differed in dignity as well as in the particular nature of their duties. The first in rank, called Archon Eponymus, or simply the Archon, represented the majesty of the state, and by his name the year of his magistracy was distinguished; the second bore the title of king, and was the head of the religion of the commonwealth, to the care and protection of which his functions principally related; and the third, or polemarch, was originally a sort of minister at war or commander-in-chief. The six other archons, denominated thesmothetes, presided as judges in the ordinary courts of justice, and formed together a tribunal with a special jurisdiction. The nine together constituted the Council of State. The legislative functions remained with the senate or *boulé* and the assembly of the people; but the whole executive powers of the state, political, military, judicial, and religious, were exercised by the archons.

Legislation of Draco.

This is the substance of the information derived from the ancient authors respecting the Athenian government at the period to which we refer; but as writing had until then been little practised in Greece, and as laws were promulgated orally and preserved by tradition, it was necessarily scanty and imperfect; nor was it possible, under such circumstances, that the sciences of legislation and government should receive any material improvement, or the rights and interests of the many meet with due respect and attention, when the authority of the state was lodged in the hands of an irresponsible few. The commonwealth was distracted by a perpetual scramble for the sovereign power, which, being open to all the principal families, some who could not obtain it by legal sought to grasp by illegal means. Factious ambition and lawless turbulence found equal scope for displaying themselves; and while the people or Demos were fearfully oppressed by the nobles, continual alternations of despotism and anarchy, of usurpation and revolution, the intolerable evils of an unsettled government and an uncertain jurisprudence, became deeply felt and almost universally acknowledged. A remedy was accordingly sought for in a written code which Draco introduced in B.C. 624; but the talents of the legislator were unequal to the task he had undertaken, and the indiscriminate severity of his system speedily defeated its own purpose. He made no attempt to reform the political constitution of his country, the real source of the miseries under which it groaned, but established a new penal code, which denounced the highest punishment against the most trivial offences as well as the most enormous crimes, upon the ground that the slightest breach of any positive law deserved death as treason against the law of the state. A system so revolting to the natural feelings and sentiments of mankind could never be reduced into practice, nor rendered productive of anything but evil; for every principle of reason and of humanity conspired to defeat its operation; and whilst its obvious tendency was to provoke the commission of heinous crimes, it at the same time multiplied the chances of impunity in favour of criminals. The laws of Draco, therefore, instead of applying a remedy to the evils of a defective system of polity, served rather to increase them, and to make the people feel strongly the necessity of a more radical and comprehensive reform than that which had been proposed by this stern and inflexible moralist. Nor was it long ere a change was effected in the constitution of the government, which laid the foundation of the Athenian system of polity properly so called, and which, though it subsequently underwent frequent and considerable alterations, may nevertheless be regarded as the basis of Athenian liberty. This was accomplished by Solon, one of the greatest characters that Greece ever produced, and one of the wisest men of whom any age or country can boast. We now accordingly proceed to give some account of his legislative labours, as these were embodied in the constitution which he reformed and remodelled on a plan suited to the circumstances and wants of his country.

Legislation of Solon.

By the fundamental law of this constitution the sovereign power was vested in the general assembly of the people. But an important question here arises, namely, Who were accounted The People, legally entitled, in their collective capacity, to the exercise of the supreme power of the state, as well as to provide effectually for the exclusion of those upon whom that high privilege had not been conferred? The population of Attica, or, in other words, the component members of the Athenian commonwealth, consisted of three classes, viz., Athenian citizens; resident aliens, or freemen liable to the capitation tax, who had not the rights of Athenian citizens; and slaves in actual bondage: and these classes differed from one another in numbers no less than in rank and condition. The number of citizens has been variously estimated, and, in point of fact, must have differed at different times. According to the census taken in the time of Pericles, they amounted to no more than 14,040 persons. In the first speech of Demosthenes against Aristogeiton, they are, however, reckoned at nearly 20,000; Plato, in his *Critias*, assumes the same amount for the most ancient times, having doubtless transferred the number that was commonly computed in his own day to the earliest periods of the state; and the later Grecian writers, as Libanius, for instance, follow the same statement. But the enumeration made by Demetrius Phalereus gives more precise and definite results. According to this census, which was taken in the year B.C. 309, there were 21,000 citizens, 10,000 resident aliens, and 400,000 slaves; an estimate which, according to the usual statistical rule of taking the adults as a fourth part of the population, would give for the total number of citizens 84,000, and for that of aliens 40,000; whilst the slaves, having no head or status of any kind in the commonwealth, are reckoned absolutely, comprehending under the 400,000 all those in actual bondage, men, women, and children, without distinction of age or sex. But, from various considerations, into which it is unnecessary to enter, Boeckh has shown[1] that this census requires considerable modifications; and, upon grounds which appear to be completely conclusive, he reckons the free inhabitants at 90,000, the resident aliens at 45,000, and the slaves at 365,000, together with women and children, which latter, however, were proportionally few. Assuming this estimate, then, as a pretty close approximation to the truth, it follows that the number of adult citizens was above 22,000, and

Population.

Attica.

that The People, in the political sense of the term, consisted of only about a twenty-third part of the entire population of the country. It is of the greatest importance to keep this fact steadily in view, as it has an immediate bearing upon the whole political system of the Athenians, and serves to reconcile many apparent anomalies by which superficial inquirers have been so often perplexed and misled. Nothing indeed can be more erroneous than the notion, which has been repeatedly promulgated, that the Athenian constitution was purely democratical. On the contrary, it was, in the strictest sense of the term, a republican aristocracy,—the whole power of the state being vested in the privileged class called citizens, who, as we have just seen, constituted but a small portion of the entire population; whilst the two other classes had no recognized political existence whatsoever, and that which was by far the most numerous remained in a state of more abject servitude than the villains under the feudal system, or the serfs in Russia and Poland.

Assembly of the people.

We have already said that, by the fundamental law of the Athenian constitution, the sovereign power was vested in the general assembly of the people. This body consisted of all the citizens, or privileged class, who had attained a certain age; excepting such as had been attainted and rendered infamous by a judicial sentence. Yielding to the temper of the times and the force of circumstances, Solon confirmed to this body an authority universally and uncontrollably absolute; but he at the same time sought to establish a balancing power, capable in some measure of restraining the excesses into which a sovereign multitude is ever ready, on the slightest excitement, to plunge. With this view he made a new division of the people into four ranks or classes, according to the relative value of their possessions or property. The first rank consisted of those whose lands produced annually five hundred medimni of corn, wine, oil, or any other commodity, dry or liquid; and who were hence called *Pentacosiomedimni*. The second rank was composed of persons whose lands yielded at least three hundred measures, and who were denominated *Hippeis*; because, although enjoying the same exemption as the first rank from service in the infantry or on shipboard, they were bound to maintain, at their own charge, a horse for the public, and, within the military age, to serve personally in the cavalry. The third rank, or *Zeugitæ*, consisted of those whose lands produced upwards of 200, but less than 300 measures, and who were bound to serve in the infantry of the line (ὁπλῖται), and to be completely provided with arms for the purpose. The rest of the citizens not possessed of lands yielding 200 measures were comprehended under the name of *Thetes*, and were also liable to military service either in the infantry of the line or among the light troops, according as they chanced to be provided with arms; and when Athens afterwards became a maritime power, it was also from this class that the fleet was principally manned. The diligent researches of Arbuthnot show the extreme difficulty, or rather impossibility, of ascertaining, by modern standards, the precise relative value of an Attic estate in the age of Solon; but it seems to be tolerably clear that the object and intention of the Athenian lawgiver in forming such division, was to give to property a preponderance over numbers, whereas hitherto all political rights had been dependent on birth alone; and, accordingly, by his constitution, it was expressly provided that the magistracies should be filled from the first, second, and third ranks, to the exclusion of the fourth. This constitution, generally called a timocracy, made the democratic element so powerful in the assembly, where every Athenian citizen, even the poorest, had a vote, that in the end it overruled every other power in the state. But, in the legislator's opinion, it was checked by two great councils, the senate of the Four Hundred and the Council of the Areiopagus.

Council of State.

The former consisted of 100 persons chosen out of each of the four wards or districts into which the people of Attica were divided, or 400 in all, but afterwards raised to 500, when the number of wards or districts was increased to ten, and 50 counsellors or senators allotted to each. This reform was introduced by Cleisthenes, in B.C. 510. The common designation of this senate was the *Boulé* or The Council of Five Hundred, or simply *The Five Hundred*. The members were chosen annually by lot from among those who were legally qualified for the office and desirous of obtaining it; but, prior to their admission, they had to undergo, before the existing council, a strict scrutiny, termed *Dokimasia*, concerning their past life, and if anything prejudicial to their character came out in course of the inquiry, they were rejected. The counsellors of each tribe, in turn, for the space of 35 days, enjoyed superior dignity and additional authority under the title of *Prytanes*; and from them the council hall or place of meeting was denominated Prytaneium. The Prytanes officiated in turn as presidents of the council, each holding the office only one day, during which he had the custody of the public seal, with the keys of the treasury and those of the citadel; and the whole assembly formed the Council of State of the commonwealth. This body, partly deliberative and partly executive, had the initiative of all laws; and, in fact, its peculiar and most important function consisted in preparing business for the assembly of the people, where nothing could be proposed which had not previously received the sanction of the council, and where the whole procedure was regulated by functionaries of its appointment. Any measure sanctioned by the *Boulé*, and thus declared to be fit to be brought before the popular assembly was termed a *probouleuma*. Attendance at the popular assemblies was made compulsory on the part of the citizens, and four assemblies were held during the presidency of every Prytaneia, or term of 35 days, for the despatch of public business, which was duly apportioned and subdivided amongst them. The first confirmed or rescinded the appointments of magistrates, received accusations of public offences presented by the thesmothete archons, and heard the catalogue of fines and confiscations for the service of the state; the second enacted laws, and disposed of petitions, public and private; the third gave audience to the ministers of foreign powers; and the fourth regulated such matters as concerned religion. In later times, all citizens who attended in due time received a small recompense or pay from the treasury. The *Epistates*, chairman, speaker, or president of the assembly, was appointed by lot from the nine *Proëdri* or foremen, who were nominated in the same way from the council, that is, one from the counsellors of each tribe whose representatives were not at the time Prytanes; and with these functionaries sat the *Nomophylaces*, otherwise called, from their number, *The Eleven*, whose duty it was to watch over the laws, and to explain to the people the tendency of any proposal which seemed contrary to the spirit of the constitution, as well as to superintend the administration of justice.

Annual revision of the laws enjoined.

Solon took none of those severe precautions to maintain his constitution which were adopted by some other ancient democratical legislators; neither exacting an oath, like Lycurgus, who by a species of artifice sought to render its obligation perpetual, nor ordaining, like Charondas, that whosoever proposed to abrogate an old law or enact a new one, should come into the assembly of the people with a halter about his neck. On the contrary, aware that regulations, however well adapted to the circumstances of the commonwealth at one period, might prove wholly unsuitable to its circumstances at another, and that time, the great innovator, rendered certain changes and modifications necessary, he even went so far as to enjoin an annual revision of the laws, and to prescribe the form in which this might with most propriety be effected. If the assembly of the people declared alteration in any point necessary, a committee was to be appointed, with directions to consider the

Attica.

change proper to be made; and if a new law was in consequence prepared, five officers were at the same time named to defend the old one before the assembly, which then decided between them. The persons composing such a committee were denominated *Nomothetes*, and in later times amounted to so many as a thousand: the persons nominated to defend an old law had the name of Syndics. This was the only form in which it was safe, or indeed constitutional, to propose any alteration in the existing law at Athens. But as the passing of a law by the assembly without the regular formalities of previous publication, or of one couched in ambiguous and fallacious terms, or contrary to a former law, subjected the proposer to penalties, it became usual to repeal the old law before any new measure was brought forward; and the delay occasioned by this double procedure served as an additional security to the constitution, which was equally guarded against rash innovation on the one hand, and the danger resulting from the absence of all improvement or amelioration on the other.

Mode of enacting a law.

The regular and ordinary mode of enacting a law at Athens may be very shortly described. As the council had the initiative of all laws, so it was their duty to frame the bills which were to be submitted to the general assembly of the people. But any citizen having aught to propose for public consideration, might address it to the Prytanes, whose duty it was to receive all petitions, suggestions, and communications, and to transmit them to the council. When the matter had been there approved and digested into proper form, it became a *probouleuma* or bill, and being written on a tablet, was exposed during several days for public perusal and consideration. At the next assembly it was read to the people, after which the question was asked by the public crier, "Who of those above fifty years of age chooses to speak?" And these, if any were so disposed, having delivered their sentiments, the crier again proclaimed, "Any Athenian, not disqualified by law, may now speak." The circumstances absolutely disqualifying were flight in battle, a large amount of debt to the commonwealth, and conviction for a crime inferring infamy; but the Prytanes had the privilege of enjoining silence at discretion, although the injunction was not effectual unless ratified or acquiesced in by the assembly. When the debates had ended, the suffrages were taken by a show of hands, which was the ordinary way of voting; but in extraordinary cases, particularly where the question to be determined related to alleged mal-administration on the part of magistrates, the votes were given by casting pebbles into vessels prepared for the purpose by the Prytanes, who, after the foremen had examined the suffrages, and declared the majority, dismissed the assembly. Such was the legislative mechanism of the Athenian constitution.

Court of Areiopagus.

But Solon hoped to provide a further and more powerful restraint against aberration in the Court of Areiopagus, by improving its regulations, and extending its powers. We have no account of the origin of this celebrated tribunal, which, indeed, the partiality of succeeding ages carried too far back into the fabulous ages to be now discovered. It was composed of those who, having executed the office of archon with credit, and passed the *euthyne* or scrutiny concerning their conduct while in power, were considered best qualified, by their experience and integrity, for being admitted members of this tribunal; and, in order to place them above being influenced either by fear or favour, they held their offices not for a year, which was the ordinary official term in the Athenian commonwealth, but for life. The powers of the court of Areiopagus were very great indeed. It is said to have been the first which adjudged the punishment of death for murder; and capital offences amongst the Athenians were for the most part cognizable by it alone. It was the only court from which there lay no appeal to the assembly of the sovereign people. It had power to stay execution of all judicial decrees, not excepting those pronounced by the general assembly itself, and to annul an acquittal or to extend mercy to the condemned; it directed all issues from the public treasury; in its censorial capacity it punished impiety, immorality, and all disorderly conduct, and exercised a general superintendence over the morals and behaviour of the people; it required every citizen to account to it annually for his means of livelihood, and to show that he earned his subsistence by honest industry in his particular calling; lastly, it took a fatherly care of the youth of the republic, and provided that all should receive an education suitable to their rank and fortune. For the despatch of judicial business the court of Areiopagus sat only during the night, and in perfect darkness, that the members, it is said, might be the less liable to prepossessions either for or against the accused; and, on the same precautionary principle, advocates were required to confine themselves to a simple narrative of facts and statement of the law, without digressing into rhetorical embellishment, or attempting to influence the understandings by appealing to the passions of the judges. In a word, this celebrated institution formed a sort of State Inquisition, and seems to have been organized for the double purpose of checking that constant tendency to excess which is inherent in all purely popular governments, and of maintaining that public and private virtue which has rightly been pronounced the principle of democracy.

Attica.

Other courts.

Besides the Areiopagus, which ought properly to be regarded as constituting part of the machine of government, there were several courts of judicature at Athens. Before the time of Solon the archons officiated as supreme and sole judges in nearly all manner of suits; but these functionaries being appointed by lot, and often very ill qualified for discharging so important a duty, it had become usual for each to choose two persons learned in the law to assist him; and the latter, under the name of *paredroi* or assessors, were at length recognized as regular constitutional officers, and appointed with the same formalities as the archons themselves. Solon, however, discerned the inconveniencies of this system, and reformed it altogether. "That," said he, "is, in my opinion, the most perfect government, where an injury to any one is the concern of all." The principle from which he set out was therefore to give to all an immediate concern in the administration of justice. With this view he ordained, that all causes should be tried by select bodies of men, resembling modern juries, and called to perform nearly the same functions; the archons merely superintending the preparation of causes, and presiding at the trial of them in the manner of our judges. All questions of law or of practice were judicable solely by the latter; but in all questions of fact, or in the general issue of guilty or not guilty, the jury were the exclusive judges; and it was the bounden duty of the presiding magistrate to give immediate effect to their decision, whatever it might be. Any Athenian above thirty years of age, and not under legal disqualification, was eligible as a juryman, on delivering his name and condition to the thesmothete archons; but as the attendance in these courts drew the citizens away from their ordinary occupations, it was only fair to indemnify them by a small payment for their attendance; this custom, however, was not introduced until the time of Pericles. From the general list of those who voluntarily tendered their services, the thesmothete archons appointed by ballot juries to their different courts; and these appear to have officiated for a definite period in each, somewhat in the manner of the Roman *judices*, who were, to all intents and purposes, a species of standing jury. It thus appears that the honour of inventing jury trial is due to the great Athenian lawgiver; and that, in his hands, the institution reached a degree of perfection which it has not yet attained among many modern nations, who affect the greatest admiration for the ancient jurisprudence, and boast of having transfused into their codes its wisest rules and provisions. It is necessary to add, that, in order to save the inhabitants of the country

the trouble and expense of resorting to Athens for justice in cases of inferior importance, itinerant judges, called from their number *The Forty*, were appointed to make regular circuits through the towns or boroughs of Attica, with full powers to judge and determine in all actions of petty assault, and in all disputes about property under a certain value.

Religion.

In all countries, and throughout all ages, religion and civil government have, with few exceptions, been so intimately, or rather so inseparably connected, that an exposition of the one would be incomplete and even unintelligible without some account of the other. The magistrate has almost everywhere sought the alliance of the priest; and the hopes and fears arising from a supposed dependence on superior power or a belief in a future state of existence have been employed as useful auxiliaries in governing men and managing their affairs in the present life. The possibility of ruling nations by means of their reason alone, and by a due regard to their secular interests, without any reference to their religious opinions or observances, is an idea which seems never to have entered the mind of any ancient legislator, and which even now, when the mighty volume of past experience is unfolded for our instruction, is considered by many as little better than downright political heresy. It was deemed alike impious and impracticable to attempt to establish any form of polity of which religion or the church did not constitute one of the main pillars, or to seek to promote the happiness of men in society without at the same time prescribing by law the mode in which they ought to worship the gods. In the Athenian constitution, as settled by Solon, religion and government, the church and the state, were so intimately connected, and became so indissolubly blended together, that, without any sensible error, we may at will consider the religion as part of the government, or the government as part of the religion, and both as alike the creatures of positive enactment or legislative ordination.

The religion of the Athenians and the Greeks generally seems to have arisen out of a strong sympathy with the various powers and agencies manifested in the visible world. To the imaginative Greek no part of nature was absolutely passive or inert; all the objects around him either impressed upon him the idea of life, or he readily imparted it to them from the fulness of his imagination. "This was, in fact, the popular mode of thinking and feeling, cherished, no doubt, by the bold forms, abrupt contrasts, and all the natural wonders, of a mountainous and sea-broken land. The teeming earth, the quickening sun, the restless sea, the rushing stream, the irresistible storm, in short, every display of superhuman power, roused in the mind of the Greek a distinct sentiment of religious awe. Everywhere he found deities, which, however, may not for a long time have been distinguished by name from the objects in which their presence was manifested. In this manner it may be supposed, the Pelasgians, or earliest inhabitants of Greece, worshipped the powers which, according to primitive notions, animated the various forms of the visible world. Herodotus, who attempts to trace the steps by which this simple belief in the divine powers of nature was transformed into the complicated system of Greek mythology, assumes two great causes of the change: first, the introduction of foreign divinities and rites; and, secondly, the inventive imagination of the Greek poets. In regard to the first point he believes, that nearly all the names of the Greek gods had been imported into Greece from Egypt; but this supposition, which was formerly adopted without scruple, and was believed in as firmly as the establishment of Egyptian colonies in Greece, has in modern times been the subject of very earnest controversies; and although it is not to be denied, that eastern nations, and even Egypt, present some striking coincidences with the religion and rites of the Greeks, yet the accounts contained in Herodotus and others who followed him are little more than dreams. As to the second point, Herodotus says that Homer and Hesiod were the authors of the Greek theogony, gave titles to the gods, distinguished their attributes and functions, and described their forms. But this opinion can be regarded as reasonable only on the supposition, that Homer and Hesiod were viewed by the historian as the representatives of a whole line of poets who were the organs and interpreters of the popular creed, and thus gradually determined its permanent form." The religion of the Greeks was in all essential points of purely native origin, but their mythology, as we now have it, must have passed through two important processes of formation. The one was that of personifying the powers of nature and conceiving them as distinct beings; the other was that by which divinities which had at first enjoyed only local worship in certain districts, or among certain tribes, were raised to the rank of national divinities, and of members of the one great family of gods. Both these processes may have been going on simultaneously, but it must certainly have taken a long period before they produced those results which we term the mythology of Greece. Although the groundwork of the Greek religion was the worship of nature and her powers, it cannot be denied that among several tribes we meet with divinities that were neither personified powers of nature, nor personified abstractions, but represented the general consciousness of man's dependence on beings of a higher order. As, however, the gods were conceived as beings with human forms, the belief that they were subject to the same passions and frailties as mortal men was a very natural consequence. But notwithstanding this, it was believed that they punished men for their offences and negligences, both in this world and in the world to come; and in this respect, it cannot be denied that the religion of the Greeks exercised a salutary moral influence. The belief in a future state was very general among the Greeks, but even the life of the blessed in the other world was not conceived by a Greek as an enviable condition at all.

Genius of this religion.

At the same time it was a system of show and parade, of festivals and ceremonies, of rites and observances, and, as such, singularly adapted to take a powerful hold of the popular mind, more especially when it became intimately blended with the literature as well as with the political institutions of the country. It imposed no particular set of doctrines, and exacted no peremptory compliances, but, addressing itself exclusively to the senses and the imagination, it was acquiesced in without inquiry, and maintained without persecution. As the religion of the state, an outward respect was due to it and required; but crimes against this religion were only punished as they affected the state, and not on the abstract grounds of impiety or sacrilege. Socrates was condemned to death, not because he revered the deity and taught a purer faith than that entertained by his countrymen, but because he attacked the religion of the state as by law established, and closely interwoven with the whole system of national policy; and even this sacrifice to the violated law was speedily and deeply repented; for the genius of polytheism was essentially tolerant. Hence mere raillery, when general and not directed against positive institutions, seldom or never incurred the animadversion of the magistrate, and was often highly relished by the people. Aristophanes, for example, made as free with the gods as he did with the great, and lashed the supposed foibles of the former with as little mercy as the vices and follies of the latter; yet his wit produced no inconvenience to its author, and was even loudly applauded by his countrymen. Æschylus, indeed, incurred some danger from a suspicion of having betrayed the secrets of Eleusis; but as this was always considered a crime of the greatest magnitude, and as it imported a violation of the most sacred human obligations, as well as of the public policy of the state in a matter where the sanctions of its laws were peculiarly severe, no inference can justly be drawn from this against the general toleration ex-

Attica.

ercised, viz., when its sallies were directed only against the public religion.

Priesthood.

Another circumstance deserving of notice is, that the ministers of religion were not confined exclusively to the service of its altars. The sacerdotal dignity was indeed incompatible with the exercise of any regular profession, and for this reason the priests had a fixed revenue secured to them; but they were eligible to the most important offices in the state, and might, if so inclined, serve as soldiers in the field. Their salaries were in general proportioned to the dignity of their functions and the rank of the deities whom they served; and these were paid out of the sacred revenues, which were derived partly from fines that individuals were condemned to pay for various offences, partly from the produce of lands consecrated to the gods, or appropriated to defray the expense of sacrifices offered in the name of the republic, partly from particular grants, and partly from a tithe of the spoils taken in war, although the last were commonly considered the exclusive property of Athena. These, with the produce of accidental confiscations, formed the regular sources of income; but the credulity of the people supplied an inexhaustible fund, which enriched the temples of Delos and Eleusis, and supported the magnificence and splendour amidst which the Delphic oracle was enshrined. The solemn festivals, such as the Dionysiac and Panathenaic, which indeed constituted the greater part of this religion, and contributed alike to maintain its hold of the popular mind and to nourish a taste for the arts, were celebrated at the expense of the choragi or leaders of the choruses, of which each tribe furnished one; and the richest citizens only were appointed to the office, which, though ruinous, was eagerly solicited, as it paved the way to more substantial honours, and formed a passport to the favour of a people ever ready to reward him who ministered profusely to their pleasures. Hence the privilege enjoyed by the choragus who had proved victorious in the scenic contests, of inscribing his name on the tripod erected by his tribe, or of perpetuating the memory of his success by a choragic monument, was not the only recompense looked for by those who had incurred the expense of ministering to the pleasures of the people. Lastly, although Athens had a state religion, it had no sacerdotal hierarchy. The priests did not, as in Egypt and in other countries, form a distinct order or caste, which, indeed, would have been incompatible with a democratical form of government. They were not a separate body united by peculiar laws under a chief whose authority extended over all its inferior members. The dignity of supreme pontiff was unknown, and each priest served his particular shrine unconnected with his brethren. The temples of the principal divinities, indeed, such as those of Athena, Poseidon, Demeter, and Persephone, had each a high priest who presided over its service; and the number of subaltern ministers employed was commonly in proportion to the rank of the particular deity, and the wealth accumulated at his shrine: but the pontifical dignity was altogether local; and the priests of one temple formed a society wholly distinct from those of another. Hence the ministers of the gods at Athens were not judges in matters of religion, nor authorized to take cognizance of or to punish crimes against the deity. This, as we have already said, was exclusively within the competency of the civil magistrate; and, accordingly, we find that it was in consequence of a civil sentence alone, and not in virtue of any power or authority in themselves, that the Eumolpidæ launched their anathemas against Alcibiades, and that Socrates was condemned to die.

Public economy. Prices.

The subject of the public economy of the Athenian state—embracing inquiries concerning prices, wages, and the interest of money; the administration of finance and the public expenditure; the ordinary and extraordinary revenues; and the peculiar financial measures of the Greeks—is too vast and complicated to be treated here at full length. In Boeckh's learned and laborious work, however, there will be found a prodigious accumulation of curious facts relative to all these branches of the subject; and although the science of the author is greatly inferior to his erudition, and his conclusions are frequently at variance with sound principle, yet he has furnished abundant means for the correction of his own errors, and collected a body of information, the value and importance of which it is difficult to over-estimate. A large part of his first book is dedicated to an enumeration of the various prices of commodities in Attica, by comparing which with the actual prices of the same commodities in different countries, he endeavours to determine the relative wealth of Attica according to modern standards. But although this collection is equally interesting and valuable, the utility of such a comparison may be fairly questioned, upon the ground that no certain inference can be drawn from the similarity or dissimilarity of ancient and modern prices. The proportion between the value of any given commodity, and that of gold or silver, may be a safe enough criterion in the same place and for short periods of time; but for distant ages and countries such a comparison can lead to no result upon which any reliance can be placed; and for this plain reason, that we have no common or invariable standard to which we can refer. For a comparison with prices in other countries at the same time, and for such a purpose as that to which Boeckh has applied it in examining the statement of Polybius respecting the valuation of Attica, his list of prices may be used with safety and advantage; but whether the precious metals, labour, or any other standard, be adopted as a medium of comparison between the prices of commodities in ancient Greece and in modern Europe, the result must, for the reason already stated, be equally fallacious and nugatory. The standard employed, whatever it may be, is itself indeterminate; or, in other words, the measure assumed and the thing to be measured by it are equally uncertain.

Attica.

Interest of money.

Again, with regard to the interest of money, it is evident that no sound conclusion can be drawn as to its rate from a consideration of the ναυτικὸς τόκος or interest of money lent on bottomry, which Boeckh takes as a criterion; because this was doubtless a most hazardous species of investment, on account of the imperfect state of nautical science, the dangerous navigation of the Greek seas, and, worse than all, the insecurity of the laws and the corruption of the tribunals; and the premium paid by the borrower to the lender would of course be in some measure commensurate with the risk to which the capital of the latter was exposed. Nor is this all. For, if the rate of interest be that sum which the lender receives and the borrower pays for the use of a certain amount of monied capital, without any consideration for trouble in the collection of the income, or for risk as to the punctual repayment of the interest or principal at stipulated periods, it may fairly be doubted whether there was anything which can justly be considered as a general or an established rate of interest at Athens. There were no public securities, no means of investing money under the guarantee of the national credit; whilst, from the continual dread of revolution or foreign invasion, the insecurity of property was such, that the punctual repayment of interest or principal at stipulated periods must have been liable to very great, but at the same time very variable, risks; a state of things wholly incompatible with a general or an established rate of interest. And with respect to money lent on mortgage or land-pledge, which, in the settled communities of modern times, approaches nearest to the public securities in point of safety, the tenure of land in Attica was, from the causes already mentioned, so precarious and insecure that, in this case also, a large yet variable indemnification, in the name of interest, must have been paid, and consequently no particular rate could have been general or common.

Revenue.

Some historians have accused the Athenian state of ne-

Attica ‖ Atticus.

glect in the administration of its finances, but without reason, as Boeckh has most conclusively shown. Of all charges, indeed, the government of Athens is the least open to that of want of diligence in exacting the utmost farthing of revenue which its available resources could by any artifice of taxation be made to afford. The ordinary revenues of the Athenian state consisted chiefly of duties arising from lands, houses, and similar property of the state, or from companies and temples; of the produce of the mines, which were public property, though commonly let in fee-farm under certain conditions, including the payment of a twenty-fourth part of the gross produce in the name of rent, and over and above the *grassum* or fine which the tenant originally paid for the lease; of customhouse-duties; of harbour-duties and market-tolls; of tithes, poll-taxes, taxes upon industry, protection-money, taxes on slaves, and taxes on prostitutes; of judicial fines and fees; of appeal-money, and fines in general; of confiscations, and tribute of various kinds; to say nothing of a variety of minor sources which it would be tedious to enumerate. The extraordinary revenues were of course variable, but arose principally from a species of property-tax, which was laid on in seasons of great emergency, when increased means were required for the defence of the state, or for the assertion of its dignity and independence. The spoils of war were also included under this head.

Mode of letting property.

Property of all kinds appears to have been commonly let upon lease; and all leases were sold by auction to the highest bidder. For this purpose the conditions of lease were previously engraved upon stone and fixed up in public. The names of the lessees were subsequently added, and the document which had been originally exhibited then became a regular contract of lease; or if not, a fresh agreement was afterwards set up. A proposal or advertisement of this kind, copied from the original document engraved on stone, is preserved in the British Museum.[1]

Attica ‖ Attorney at-Law.

The history of Greece, and in particular that of Attica, has been treated of late years with greater ability, more learning, and sounder views, than at any previous period since the revival of letters. German scholars have produced innumerable treatises upon all subjects connected with the history of Attica, but at no time and in no country has ancient Greece found historians equal to Thirlwall and Grote. The work of the former appeared first in Lardner's *Cabinet Cyclopædia*, in 8 vols. 12mo; a second and improved edition in 8 vols. 8vo, appeared in London, 1845–52. Of Mr Grote's history only 11 vols. have as yet been published, but a 12th, carrying the history down to the death of Alexander the Great, will complete the work. Niebuhr's *Lectures on Ancient History* (edited by Dr L. Schmitz, London, 1852, in 3 vols.) are, like all Niebuhr's Lectures, of the highest interest and importance. In regard to the literature of Greece, the work of Colonel Mure, of which 3 vols. have already appeared, will be a worthy companion to the works of Bishop Thirlwall and Mr Grote. (J. B—E.) (L. S.)

ATTICUS, Herodes, an opulent citizen of Athens, in the time of the Antonines, celebrated for the vast sums he expended in the decoration of that and other cities. He built a stadium at Athens, 600 feet in length, of Pentelican marble, capable of containing at once the whole population; and erected a new theatre or odeion in honour of his deceased wife Regilla. The aqueduct of Troas in Asia was completed by him at an expense of more than L.100,000 sterling; at Corinth he built a theatre, and richly decorated the temple of the Isthmean Neptune. The stadium at Delphi was another of his works; as were the baths of the hot-springs at Thermopylæ; and a fine aqueduct at Canusium in Italy. Many cities of Peloponnesus, Bœotia, Epirus, Thessalia, and Eubœa have, by numerous inscriptions, testified their gratitude to him, their munificent benefactor. See *Mem. de l'Acad. des Inscrip.* xxx., and Gibbon's *Hist.* i.; Stuart's *Athens*, where its dimensions and plan are given.

Atticus, *Titus Pomponius*, one of the most distinguished Romans of his time, who, without in any degree compromising his neutrality, preserved the esteem and affection of all parties. His strict friendship with Cicero did not prevent him from being at the same time on terms of great intimacy with Hortensius. He steadily declined any interference in public affairs, though his talents and immense wealth might have secured him the highest dignities of the state. The contests at Rome between Cinna's party and that of Marius induced him to retire to Athens, where he continued for a considerable time. From this circumstance, and his thorough acquaintance with Greek learning, he derived his surname of *Atticus*. His passion for books led him to the collection of a magnificent library, in which he kept a number of copyists constantly employed. He wrote, besides other pieces, *Annals*, or *A History of Rome*, embracing (as we learn from Cicero) a period of 700 years; but none of his writings are extant. At the age of 77 he anticipated the consummation of an incurable disease, by abstaining from food, in consequence of which he died upon the fifth day, B.C. 32.—Cornelius Nepos; Cicero *ad Att.*

ATTIGNY, a small town of France, in the department of Ardennes, on the left bank of the river Aisne, 22 miles S.W. of Mezieres. It was a place of some celebrity at an early period, from its being usually selected as the summer residence of the kings of France. Pop. 1365.

ATTILA, king of the Huns. See Roman History.

ATTLEBOROUGH, a market-town in the hundred of Shropham, county of Norfolk, 14 miles from Norwich. It is said to have been formerly a large city, the capital of the county, and at one time had a college. Pop. of parish in 1851, 2324.

ATTOCK, a celebrated town and fort of Hindustan, in the Punjaub, on the eastern bank of the Indus, in Long. 72. 20. Lat 33. 54. The locality is of importance, both in a military and commercial point of view, as the Indus is here crossed by the great route which, proceeding from Cabool eastward, through the Kyber pass into the Punjaub, forms the main line of communication between Afghanistan and Northern India. The river was here repeatedly crossed by the British armies during the late military operations in Afghanistan; and, according to the general opinion, it is the place where Alexander, Tamerlane, and Nadir Shah crossed the river in their respective invasions of India. The Emperor Akbar built the present fortress in 1851. (E. T.)

ATTORNEY-AT-Law is one who is put in the place, stead, or *turn* of another (*attornatus*), to manage or conduct his law proceedings or affairs. The term is used in England to denote the class of legal practitioners whose functions are preparatory to those of the barrister or advocate. See Agent.

Before the statute of Merton, 28th Hen. III., c. 10, which authorized any freeman to make attorney, every suitor was obliged to appear in person to prosecute or defend his suit (according to the old Gothic constitution), unless by special license under the king's letters-patent; and at present it is the common course for the plaintiff and defendant to appear by attorney, upon the principle of convenience, in the same manner as, according to Justinian, took place

[1] This inscription was first published by Chandler from a most inaccurate transcript, together with a Latin version, also very indifferently executed. It was afterwards given by Boeckh, in the appendix, to his *Staatshaushaltung der Athener*, where he corrected many of Chandler's errors; and he has since repeated it with some additional improvements in his Corpus of Greek Inscriptions, p. 141. The date, mutilated at the end, is either Olymp. 114. 4, or 115. 3.

Attorney-at-Law || Attraction.

in the Roman law. But an infant, a married woman, or an idiot, cannot appear by attorney, but in person or by guardian, according to the nature of the case, although an attorney be employed on their behalf.

By the 6th and 7th Vict., c. 73, the qualifications necessary for admission on the rolls of attorneys and solicitors are :—1*st*, The due execution of a proper contract in writing with some practising attorney or solicitor for the term of five years, or of three years if the clerk be a graduate of the universities of Oxford, Cambridge, Dublin, London or Durham, or of the Queen's University, Ireland (14th and 15th Vict., c. 88); 2*d*, The payment of the stamp-duty on such contract, amounting to L.120; 3*d*, The registry or enrolment of the contract within six calendar months; 4*th*, Actual service for the prescribed period in the proper business of an attorney and solicitor, but one year may be served with the London agent, and, where the service is for five years, another year with a barrister or certificated special pleader; 5*th*, Due notices of the application to be admitted; 6*th*, Fitness and capacity ascertained upon examination, and certified by the examiners; 7*th*, Taking the prescribed oaths, and being admitted and enrolled; 8*th*, The certificate of the registrar of attorneys that he is duly enrolled, and the stamped certificate of the annual payment of the duty.

Persons admitted in one court, may be admitted in any other court, on producing the necessary certificates, and signing the roll of the other court.

No attorney is to have more than two articled clerks at one time, nor to take or retain any clerk after discontinuing business, nor whilst clerk to another; and in case the attorney should become bankrupt, or be imprisoned for 21 days, the court may direct the articles of clerkship to be discharged or assigned; and where the master dies the clerk may enter into a fresh contract for the residue of the term.

Under section 29 of the act, applications to strike attorneys off the roll for defect in their articles, are to be made within 12 months after admission, but in case of fraud, the application may be made at any subsequent period.

Attorney-General || Attraction

Attorneys, if prisoners, are not to commence, prosecute, or defend any suit or action in any court of law or equity, or matter in bankruptcy, and offenders are to be deemed guilty of a contempt of court, and unable to recover their fees; nor are they to act as agents for unqualified persons, and if so acting, they are liable to be struck off the roll. (R. M—M.)

ATTORNEY-GENERAL is a great officer under the crown, made by letters-patent, and is generally chosen from Her Majesty's counsel learned in the law. It is his place to exhibit informations, and prosecute for the crown, in matters criminal; and to file bills in the exchequer, for anything concerning the crown in inheritance or profits.

The attorney-general, under the royal mandate of 14th Dec., 1813, has place and audience before the premier serjeant. In 1834, the lord advocate of Scotland claimed precedence in the House of Lords of the attorney-general. The point was decided in favour of the attorney-general, but it was admitted that the lord advocate was entitled to precedence of the solicitor-general.

His proper place in court, upon any special matters of a criminal nature, is under the judges, on the left hand of the clerk of the crown; but usually he sits in the face of the court and the centre of the inner bar of Queen's counsel. (R. M—M)

ATTRACTION.

THE word Attraction is used to denote what we observe when one body approaches another, or tends to approach it, without any apparent impulse or other cause to which the motion can be ascribed.

General observations.

We have instances of attraction when iron approaches the magnet, when certain bodies are placed near an excited electric, and when a stone falls to the earth. We say likewise that the earth attracts the moon; by this mode of expression meaning no more than that the moon is continually deflected towards the earth, from the rectilineal course which it would otherwise pursue. It is likewise in this sense that we must be understood when we say that the sun attracts all the planets.

In the instances already mentioned, attraction extends to a distance. In other cases it is confined within limits so extremely narrow as to become imperceptible at an interval which cannot be appreciated by the senses. Of this kind is the attraction which takes place between the particles of the same fluid, as is apparent from the round figure of small drops. To this class likewise belongs the attraction between fluid and solid bodies; whence originate the very interesting appearances observed in capillary tubes, and other kindred phenomena. An attraction between the small elementary particles of all solid bodies is manifest from the force with which they cohere or resist an endeavour to separate them. In many cases the intensity of this force is prodigiously great in contact or at the nearest distances; while it ceases to act upon making the smallest separation between the parts. Lastly, chemistry developes innumerable instances of attraction between the molecules of the bodies about which it is conversant; insomuch that it is to this principle, under the name of affinity, that we must ultimately ascribe the various decompositions and new combinations which occur in that science.

All these phenomena, although very different from one another in other respects, have yet this in common, that we observe in certain bodies a tendency to approach one another, and to resist a separation, with some degree of force. The facts are certain, and are attended with no ambiguity; and it is to express these facts that the term *attraction* is used in physics.

We likewise observe, in some bodies, a tendency to fly off from one another when they are brought near. This is called *repulsion*.

The word *force* has, in general, some degree of obscurity. It is used to denote the cause of motion; but we have no direct knowledge of it, and we judge of its intensity by the effect which we suppose it to produce. In all our reasoning concerning forces, it is the changes of motion which we measure and compare together, and which are really the subjects of our thoughts. Attraction and repulsion are forces or principles of motion, known to us only by the phenomena we observe; but the circumstance of their implying action at a distance is an additional source of obscurity in which other kinds of force do not participate.

It certainly is inconceivable that motion should be produced at a distance, when no connection can be traced between the body moved and that which is supposed to produce the motion. We are strongly impressed with the prejudice, that a body cannot act but where it is; and we find difficulty in admitting that the mere presence of two bodies, without the intervention of any mechanical means, can be a satisfactory cause of motion. On this account attraction has been classed by some with the occult qualities of the schools; and the favourers of this doctrine have been reproached with reviving exploded notions in philosophy. Impulse is a principle of motion more familiar to us, and to which we are not disposed to make equal objection. Whenever the communication of motion can be traced to this source, we are satisfied that the effect is justly explained. Hence many philosophers have been of opinion, that impulse is the only cause of motion that ca

Attraction. be admitted in physical science; and many attempts have accordingly been made to reduce to this principle all cases in which distant bodies act on one another. With regard to these attempts, it will be sufficient to remark here, that they are all built upon hypothesis. No evidence is adduced to prove that such things exist as the elastic ether or gravific matter which they set out with supposing. And, as far as such systems have no other object than to obviate the difficulty of action at a distance, this argument alone is sufficient to confute them, without adverting to the difficulties that attend each of them separately, their inconsistency with the received laws of motion, and the innumerable contradictions and improbabilities to which they are liable on every side.

A little reflection is sufficient to show that, in reality, we have no clearer notion of impulse as the cause of motion than we have of attraction. We can as little give a satisfactory reason why motion should pass out of one body into another on their contact, as we can, why one body should begin to move, or have its motion increased, when it is placed near another body. It is equally impossible in both cases to prove that there is a necessary connection between the related facts; and in this respect both the phenomena are alike inexplicable.

When motion is produced by impulse, it is probably the circumstance of contact apparently taking place which leads us to think that the effect is so clearly explained. It is in this manner only, or by actual contact, that we ourselves can move external objects. We have no power of producing motion in distant bodies, except by the intervention of other bodies on which we act immediately. Impulse is, therefore, a cause of motion familiar to us, and strikes us as the plainest and most satisfactory ultimate principle at which we can arrive. On the other hand, when one body attracts another at a distance, there is nothing familiar to us with which we can compare it; our curiosity is excited, and we are led to seek out some hidden connection between them.

But it may be doubted whether there is actual contact in any case of the communication of motion. When a body is impelled by the air, it will hardly be affirmed that the particles of that elastic fluid are in contact with one another, since there is no space, however small, within which a given bulk of it may not be compressed, by applying an external force sufficiently great. The particles of air, therefore, act on one another at a distance; and the same thing must be true of all other elastic fluids. And, by the way, what is here said is sufficient to prove, that no scheme, founded on the hypothesis of an elastic ether, will enable us to account for attraction; because such a contrivance can do nothing more than substitute one species of action at a distance instead of another. There is good reason to think that absolute contact never takes place in the component parts of the hardest and most compact solid bodies. This seems to be an unavoidable consequence of the fact, well established by experience, that all bodies contract in their bulk by cold, and expand by heat. It is therefore not only not impossible, but it is even in some degree probable, that the communication of motion may, in every instance, be a case of action at a distance.

If, then, we are apt to think that impulse is a clearer physical principle than attraction, there is in reality no good ground for the distinction; it has its origin in prejudice, and in our mistaking the proper object of natural philosophy. All our researches in nature are confined to the phenomena we observe, and to the laws by which they are regulated. A physical cause is no other than a general fact discovered by a careful observation and an attentive comparison of many particular and subordinate facts. We have no evidence, independent of experience, that any consequence, deduced from a physical cause, will actually take place. There is in this case no necessary connection from which we can, with absolute certainty, infer the expected event. If, then, we regard impulse and attraction as principles founded in fact, and regulated by laws confirmed by observation and experiment, they are both equally entitled to be classed as physical causes, and they ought both to be admitted as of equal authority in explaining the phenomena of the universe. Attraction.

If we turn our attention to the different kinds of attraction enumerated above, and inquire what progress has been made in the investigation of their laws of action, we shall find that, generally speaking, this branch of physics has been little advanced. We are very imperfectly acquainted with magnetical and electrical attraction. We know still less of those attractive powers which take place at small distances, and which are confined within such narrow limits that their mode of action escapes the observation of our senses. Attraction is, indeed, much used by philosophers to account for many important natural phenomena; but their explanations are often vague, and destitute of that precision which ought always to be aimed at in physical science. There is only one class of phenomena in which the laws of attraction have been fully developed. We allude to gravitation, that principle which occasions the fall of heavy bodies at the surface of the earth, and which retains the planets and comets in their orbits. Referring the other species of attraction, which are little susceptible of general discussion, to their several heads, we shall now confine our attention to gravitation

Discovery of the law of gravitation.

Traces of the principle of gravitation are to be found in writers of great antiquity; but their speculations on this subject do not go beyond a vague notion of a tendency which the planets have to one another, or to a common centre. It would contribute little either to entertainment or instruction to collect all the passages of ancient authors that speak of this principle. The revival of the true system of the world by Copernicus introduced the most admirable simplicity in the explanation of the planetary motions, and likewise led to more just conjectures concerning the laws by which they are upheld. Copernicus himself attributed the round figure of the planets to a tendency which their parts possess of uniting with one another, thus extending to all the planets that attraction which we observe at the surface of the earth. He stopt short indeed at this point, conceiving attraction to be confined to the matter of each planet, without making it extend from one planet to another, so as to actuate all the bodies of the system. This step was made by the bold and systematic genius of Kepler. Adopting the opinion of Dr Gilbert of Colchester, that the earth is a great magnet, Kepler formed to himself a notion of attraction, in some respects remarkably just. He says that the earth and moon attract one another, and, were it not for some powers which retain them in their orbits, they would move towards one another, and would meet in their common centre of gravity. He attributes the tide to the moon's attraction (*virtus tractoria quæ in luna est*), which heaps up the waters of the ocean immediately under her. But in many respects his notions of attraction were fanciful and extravagant; a more perfect knowledge of the laws of motion than had been attained to in his time, and a new geometry, were both wanting in order to guide him in this research without danger of wandering. Yet he was able to penetrate so far into the causes of the planetary motions, as to foresee that they would not long continue latent; and he tells us, he was persuaded that "the full discovery of those mysteries was reserved for the next age, when God

Attraction. would reveal them." So full an exposition of a physical system of the world as is contained in the writings of Kepler could not fail to draw the attention of succeeding philosophers. Many remarks concerning the principle of gravitation are to be found in the writings of Fermat, Roberval, Borelli, and other authors; but no one before Newton entertained so clear and systematic a view of the doctrine of universal gravitation as Dr Robert Hooke. In his work on the motion of the earth, published in 1674, twelve years before the appearance of Newton's *Principia*, he lays down these three positions as the foundations of his system, viz.:—

"1*st*, That all the heavenly bodies have not only a gravitation of their parts to their own proper centre, but likewise that they mutually attract each other within their spheres of action.

"2*dly*, That all bodies having a simple motion will continue to move in a straight line, unless continually deflected from it by some extraneous force, causing them to describe a circle, or an ellipse, or some other curve.

"3*dly*, This attraction is so much the greater as the bodies are nearer."

The principle of universal gravitation is here very precisely enunciated. Dr Hooke seems to have clearly perceived that the planetary motions are the result of an attraction towards the sun, and of a rectilineal motion produced by a projectile force. Not having discovered the law according to which the force diminishes as the distance from the sun increases, he contrived experiments to elucidate his theory. Having suspended a ball by means of a long thread, he placed another ball upon a table immediately under the point of suspension, and he caused the suspended ball to revolve round the stationary one. When the movable ball was pushed laterally with a force properly adjusted to its deviation from the perpendicular, it described an exact circle round the ball on the table: in other cases it described an ellipse, or an oval resembling an ellipse, having the other ball in the centre. Dr Hooke observed, that although this experiment in some measure illustrated the planetary motions, yet it did not represent them accurately; because the ellipses which the planets describe have the sun placed in one focus, and not in the centre. Thus, at the appearance of Newton, many things were known, or rather surmised, that prepared the way for the discovery of the principle which regulates the celestial motions. This does not detract in any degree from the glory of Newton, who, discarding the conjectures of his predecessors, proposed to himself to investigate, with mathematical strictness, the law of the attractive force, and to ascertain with precision its sufficiency to retain the planets in their orbits. He invented a new kind of geometry, which was necessary to enable him to accomplish his purpose. With this help, and by admitting nothing without the sanction of the established principles of Dynamics, he deduced from the motions of the celestial bodies the law of universal gravitation, the most important and the most general truth hitherto discovered by the industry and the sagacity of man, viz. "that all the particles of matter attract one another, directly as their masses, and inversely as the squares of their distances."

Having arrived at a principle which belongs to every part of matter, another inquiry comes into view. Setting out from this principle, it is now necessary to proceed in an inverted order, and deduce from it, by synthetical reasoning, the phenomena which we observe in the universe. The first step in this process is to find out the attractive force of the planets, which arises from the united attractions of their component parts. Two things only are involved in this investigation, viz. the known law of attraction between the particles of matter, and the figure of the attracting bodies. This is a subject of great importance, and it is connected with some principal points of the system of the world, with the theory of the figure of the planets, that of the tides, and many other phenomena. It is but imperfectly discussed in Newton's immortal work; and there is no part of his philosophy which has been improved more slowly by the labours of his followers. We now propose to treat of it at some length, endeavouring to lay before our readers as complete a view of this part of science as the nature of our work will permit. Attraction.

We begin with laying down some definitions, and demonstrating some properties, of elliptical spheroids. Definition and properties of elliptical spheroids.

Def. 1. A solid generated by the revolving of an ellipse about either axis is called a spheroid of revolution. If the ellipse revolve about the less axis, the spheroid is oblate; if about the greater axis, it is oblong.

Let k and k' denote the two axes of the spheroid, k being that of revolution; and let x and y be two co-ordinates of a point in the surface of the spheroid, having their origin in the centre, x being parallel to the axis of revolution, and y perpendicular to it; then the equation of the spheroid, whether oblate or oblong, will be

$$\frac{x^2}{k^2} + \frac{y^2}{k'^2} = 1.$$

Def. 2. An elliptical spheroid, in general, or an ellipsoid, is a solid bounded by a finite surface of the second order. Let ACB and ADE (Plate CI. fig. 1: this figure represents one eighth of an ellipsoid contained in one of the solid angles formed by the three principal sections) be two ellipses that have the same axis AO, the same centre O, and their planes perpendicular to one another: from any point K in the common axis, let there be drawn ordinates in both ellipses, as KC and KD; then, having described an ellipse of which KC and KD are the semiaxes, the periphery DMC of that ellipse will be in the surface of the ellipsoid. This solid figure has a centre, three axes crossing one another at right angles in the centre, and three principal sections made by planes passing through every two of its axes.

Let k, k', k'', denote the three semiaxes, viz. $k = \mathrm{OB}$, $k' = \mathrm{OE}$, $k'' = \mathrm{OA}$; and let x, y, z, denote three rectangular co-ordinates of a point M in the surface, the co-ordinates being parallel to the axes, and having their origin in the centre, viz. $\mathrm{MN} = x$, $\mathrm{NK} = y$, and $\mathrm{OK} = z$; then the equation of the surface will be $\frac{x^2}{k^2} + \frac{y^2}{k'^2} + \frac{z^2}{k''^2} = 1$; as it is easy to prove from the foregoing construction.

The ellipsoid becomes a sphere when all the three axes are equal: it becomes a spheroid of revolution when two of them are equal.

1. *If any plane cut an elliptical spheroid, the section will be an ellipse. In the spheroid of revolution, a section made by a plane perpendicular to the axis of revolution is a circle.* All this follows so easily from the nature of the solids, that we need not stop to give a formal demonstration.

2. *If a straight line cut two concentric ellipses that are similar and similarly situated, the parts of it between the outer and inner peripheries are equal to one another.*

Let AHBK and MDNC (Plate CI. fig. 2) be two similar and similarly situated ellipses that have the same centre O; and let the straight line AB cut them both; then AC and BD are equal. Bisect CD in L, and through L and the common centre draw the straight line HMNK to cut both ellipses. Because the ellipses are similar and similarly situated, and that CD is an ordinate of the diameter MN, it is plain that AB will be an ordinate of the diameter HK; wherefore, AB and CD being both bisected in L, AC is equal to BD.

Attraction. 3. *If there be two ellipses, one within the other, such that, any straight line being drawn to cut them, the parts of it between their peripheries are equal to one another, these ellipses are concentric, similar, and similarly situated.*

Let D (fig. 2) be any point in the inner ellipse, and through D draw EF, terminating in the outer ellipse: then, if we make FG = DE, G must be a point in the inner ellipse. Hence all the points of the inner curve are determined when the outer ellipse and the point D are given: wherefore there cannot be two different curves, both passing through D, that will answer the conditions. But an ellipse described through D, concentric with the outer ellipse, and similar to it, and similarly situated, will answer the conditions (2). Wherefore the two ellipses are concentric, and similar, and similarly situated.

4. *If a straight line be drawn to cut two elliptical spheroids that have the same centre, and are similar and similarly situated, the part of it between the outer and inner surfaces will be equal to one another.*

Conceive a plane, which contains the straight line, to pass through the common centre of the solids: the sections made by the plane will be concentric ellipses (1); and these will be similar and similarly situated, because the solids are so: wherefore the parts of the straight line between the surfaces are equal (2).

5. *If two elliptical spheroids that have the same centre, and are similar and similarly situated, be cut by a plane, the two sections will be concentric ellipses that are similar and similarly situated.*

For the sections are ellipses (1); and, any straight line being drawn to cut them, the parts of it between the peripheries will be equal (4). Wherefore the ellipses are concentric, similar, and similarly situated (3).

6. *Let ADE and CFG* (fig. 3) *be two concentric ellipses that are similar and similarly situated; let AO and CO, in the same straight line, be two of their axes, and let DE, drawn through C, be perpendicular to AO; then if CF and CG be two chords of the interior ellipse that make equal angles with the axis CO, and if the chords DM and DN of the exterior ellipse be drawn respectively parallel to CF and CG; the sum of CF and CG will be equal to the sum or difference of DM and DN, according as they both fall on the same side, or on different sides of DE.*

For draw EP parallel to CF, and it will likewise be parallel to DM. Because CF and CG are equally inclined to CO and to DE, it is plain that DN and EP, which are parallel to CF and CG, are likewise equally inclined to DE: consequently DN = EP. Draw a straight line through the common centre to bisect DM in L, and that straight line will likewise bisect EP, parallel to DM, in H: and because the ellipses are similar and similarly situated, the same straight line will likewise bisect the chord CF of the interior ellipse, in K. Because DC = CE, therefore DL + EH = 2CK = CF. Wherefore DM + DN = 2DL + 2EH = 2CF = CF + CG.

The demonstration of the other case, when DM and DN fall on different sides of DE, is entirely similar.

Some general Properties, resulting from the Law of Attraction that obtains in Nature.

7. *Let AB and EF* (fig. 4) *be two indefinitely slender pyramids, that are similar to one another, and both composed of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance: the attractions of the pyramids upon particles placed at the vertices A and E are proportional to the length of the pyramids.*

Conceive each of the pyramids to be divided into an indefinitely great number of thin slices of equal thickness, by planes parallel to its base; then, if CD and GH be any two of these slices, their attractions upon particles placed at A and E will be proportional to $\frac{CD}{AC^2}$ and $\frac{GH}{EG^2}$: Now, Attraction. these are equal; for the solids CD and GH having the same thickness, they are proportional to the sections CM and GN, that is, to AC^2 and EG^2, because the pyramids are similar. Wherefore the attraction of any one of the slices in the pyramid AB, upon a particle placed at A, is equal to the attraction of any one of the slices in EF upon a particle placed at E. Consequently, the whole attraction of the pyramid AB is to the whole attraction of the pyramid EF as the number of slices in AB to the number of slices in EF, that is, as the length AB to the length EF.

Cor. 1. The attractions of any portions of the pyramid are as the lengths of the portions. For the attractions are proportional to the number of slices in the portions, that is, as the lengths.

Cor. 2. If the pyramids have different densities, their attractions are proportional to the lengths multiplied by the densities. For, in this case, the attraction of each slice will be proportional to its density; wherefore the attractions will be as the densities multiplied by the number of slices, or as the densities multiplied by the lengths.

8. *If there be two similar solids composed of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance; any two particles of matter, similarly situated with regard to the solids, will be attracted by them with forces that are proportional to any of the homologous lines of the solids.*

Because the solids are similar, they may be resolved into an indefinitely great number of slender pyramids, and frustums of pyramids, that are similar to one another, and similarly placed in the solids; each pyramid having its vertex at one of the attracted particles. The direct attractions of any corresponding pair of pyramids will have constantly the same ratio to one another; for they will be as the lengths of the pyramids or frustums (7); that is, because the solids are similar, as any two homologous lines of the solids. Wherefore the whole attractive forces, compounded of all the direct attractions which act in directions that make the same angles with one another, will likewise have to one another the proportion of any two of the homologous lines of the solids.

Cor. If the two solids have different densities, their attractions will be proportional to the densities multiplied by any homologous lines of the solids (7, *Cor.* 2).

9. *If there be two concentric elliptical spheroids that are similar and similarly situated, a particle placed anywhere within the inner surface will be in equilibrium, or will be urged equally in all opposite directions by the shell of homogeneous matter contained between the two surfaces, supposing the law of attraction to be that of the inverse proportion of the square of the distance.*

Let P (Plate CI. fig. 5) be a particle placed within such a shell, and let a slender double pyramid, having P for the common vertex, be extended to meet the surfaces of the solid on both sides of P. The portions of the pyramid AGHB and CEFD between the surfaces on opposite sides of P, will have equal lengths (4); wherefore these portions will attract a particle placed at P with equal forces (7, *Cor.* 1). The same thing may be proved of all the pyramids which have their vertices at P, and fill the spheroids. Wherefore P is attracted equally in all opposite directions by the homogeneous matter contained between the surfaces of the spheroids.

10. *To find the attractive force of an indefinitely slender prism, acting in a direction parallel to the prism, upon a particle of matter placed anywhere.*

Let BC (Plate CI. fig. 6) be a prism of homogeneous matter, upon the indefinitely slender base CH, and

Attraction. let a particle of matter be placed at A; draw AB and AC to the extremities of the prism, and AE to any point in it; and draw AD perpendicular to BC. Let S = base CH, and put AD = a, DE = x; the element of the prism is = S × dx, the element of the attraction in the direction AE is = $\frac{S \times dx}{AE^2}$, and the element of the attraction in the direction parallel to the prism is = $\frac{S \times dx}{AE^2} \times \frac{DE}{AE} = \frac{S \times x dx}{(a^2+x^2)^{\frac{3}{2}}}$.

Now, $\int \frac{S \times x dx}{(a^2+x^2)^{\frac{3}{2}}} = \text{Const.} - \frac{S}{\sqrt{a^2+x^2}} = \text{Const.} - \frac{S}{AE}$; and the constant quantity is determined by making the fluent begin at the end of the prism nearer to A; wherefore the whole attractive force of the prism, in the direction parallel to the prism, is

$$= S \times \left\{ \frac{1}{AB} - \frac{1}{AC} \right\}.$$

Cor. In like manner may the attractive force of the prism be found, when the attraction of the particles is proportional to any function of the distance.

Let AB = f, AC = f'; suppose that $\varphi(f)$ is the function of the distance that expresses the law of attraction; and put $\int df \cdot \varphi(f) = \Psi(f)$; then the attraction parallel to the prism is

$$= S \times \pm [\Psi(f) - \Psi(f')],$$

observing that the attraction is always positive.

ATTRACTION OF SPHERES.

Attraction of spheres. 11. *Spheres of the same homogeneous matter attract particles placed on their surfaces with forces proportional to their radii.*

Spheres being similar solid figures, this proposition is no more than a particular case of what was before proved (8).

Cor. If the spheres have different densities, the attractions at their surfaces are proportional to their radii multiplied by their densities. (8, Cor.)

12. *The force with which a particle, placed anywhere within a sphere of homogeneous matter, is urged towards the centre, is proportional to its distance from the centre.*

Conceive a concentric sphere to be described, which contains the attracted particle in its surface; the matter between the two surfaces will exert no force on the particle (9), which will therefore be urged to the centre, only by the attraction of the inner sphere, in the surface of which it is placed; but this force is proportional to the radius of the sphere, or to the distance of the particle from the centre (11).

13. *Let PNQ and ABC* (fig. 7) *be two spheres of the same homogeneous matter, which attracts in the inverse proportion of the square of the distance; let the centres of the spheres be at M and D, and take MR equal to the radius of the sphere ABC, and ED equal to the radius of the sphere PNQ; the attractions of the spheres upon particles placed at R and E are to one another as the squares of the radii of the spheres.*

In the spheres draw two great circles perpendicular to the diameters PQ and AC, that pass through the points R and E; and let PpQ and AbC be two great circles, making equal indefinitely small angles NMp and BDb with the great circles PNQ and ABC. Let HK and FG, parallel to PQ and AC, be any two chords of the circles PpQ and AbC, that subtend similar arcs, or arcs containing the same number of degrees; and through HK and FG let planes perpendicular to the circles PpQ and AbC, be drawn to cut the portions of the spheres contained in the angles NMp and BDb; join RH, RK, MH, MK, DF, DG, EF, EG. Because the arcs subtended by HK and FG are like parts of their circumferences, it is plain that the angle RMH = EDF, and RMK = EDG. And because ED = MH = MK, and RM = DF = DG (*hyp.*), therefore RH = EF, and RK = EG.

Conceive the chords HK and FG, together with the planes passing through them, to change their place a little, so as to describe two slender prisms, or elements of the portions of the spheres contained in the angles NMp and BDX. It is plain that MX and DO, the distances of the chords HK and FG from the centres of their circles, are constantly proportional to MN and DB, the radii of the spheres; wherefore XT and OS, the perpendicular sections of the small prisms, are similar figures, and have to one another the same ratio that MX² has to DO², or MN² to DB². Now, the attraction of the prism HK urging a particle at R to the centre M, is

$= XT \times \left(\frac{1}{RH} - \frac{1}{RK}\right)$, (10); and the attraction of the prism FG urging a particle at E to the centre D, is $= OS \times \left(\frac{1}{EF} - \frac{1}{EG}\right)$. But in consequence of what was proved, $\frac{1}{RH} - \frac{1}{RK} = \frac{1}{EF} - \frac{1}{EG}$; wherefore the attractions of the prisms are to one another as XT to OS, or as MN² to DB². The same thing may be proved of all the elements of the two portions of the spheres contained in the angles NMp and BDb; wherefore those portions attract particles at R and E with forces proportional to the squares of the radii of the spheres. But because the small angles NMp and BDb are equal, each of the spheres may be divided into an equal number of such portions; wherefore the attractions of the whole spheres upon particles placed at R and E are proportional to the squares of the radii of the spheres.

Cor. This proposition is true when the particles of matter attract one another with forces proportional to any proposed function of the distance.

Let RH = EF = f, and RK = EG = f'; then, adopting the same notation as before (10, *Cor.*), the attractions of the prisms urging particles placed at R and E to the centres M and D, are respectively XT × ± $[\Psi(f) - \Psi(f')]$, and OS × ± $[\Psi(f) - \Psi(f']$: consequently, those attractions have the same proportion that XT has to SO, or MN² to DB². Wherefore the attractions of the whole spheres are in the same proportion.

14. *A particle placed anywhere without a sphere of homogeneous matter which attracts in the inverse proportion of the square of the distance, will be urged to the centre of the sphere with a force that is inversely proportional to the square of the particle's distance from the centre.*

Let ABC (Plate CI. fig. 8) be the sphere, O its centre, and P a particle without the sphere: conceive a concentric sphere PMN, of the same homogeneous matter with the sphere ABC, to be described with the radius PO. Then, by the last proposition, the attraction of the sphere ABC upon the particle P is to the attraction of the sphere PMN, upon a particle placed at A, as AO² to PO². But the attraction of the sphere PMN upon a particle placed at A is equal to the attraction of the sphere ABC upon the same particle; for the attraction of the matter between the two spherical surfaces exerts no force upon a particle at A (9). Wherefore, in the proportion set down above, the two middle terms are con-

Attraction. stantly the same wherever the point P is placed without the sphere ABC; consequently the first term of the proportion must follow the inverse ratio of the last term; that is, the attraction of the sphere ABC upon the external particle at P is inversely proportional to PO^2.

15. *The same law of attraction being supposed, a homogeneous sphere will attract a particle placed without it, with the same force as if all the matter of the sphere were collected in the centre.*

Let f denote the distance of the particle from the centre; then it follows, from the last proposition, that the attraction of the sphere upon the particle will have for its measure $\frac{A}{f^2}$; A denoting a constant quantity that will be determined by any particular case; that is, by the actual attractive force corresponding to any determinate distance from the centre. Let r denote the radius of the sphere, and M its mass; then no part of the matter of the sphere being nearer the attracted particle than $(f-r)$, and none of it more remote than $(f+r)$, the attraction of the sphere on the particle will be greater than $\frac{M}{(f+r)^2}$, and less than $\frac{M}{(f-r)^2}$. Therefore $\frac{A}{f^2}$ is always contained between those limits, which requires that A = M. For, if A were greater than M, such values of f might be found as would make $\frac{A}{f^2}$ equal to or greater than $\frac{M}{(f-r)^2}$; and if A were less than M, such values of f might be found as would make $\frac{A}{f^2}$ equal to or less than $\frac{M}{(f+r)^2}$. Therefore A = M; and the attraction of the sphere is equal to $\frac{M}{f^2}$, or the same as if all the matter were collected in the centre.

If the radius of the sphere = r, the density of the matter contained in it = d; then the mass, or M, = $\frac{4\pi r^3 d}{3}$ (π being the circumference of the circle whose diameter is unit), and the attraction of the sphere at the distance f from the centre = $\frac{4\pi r^3 d}{3f^2}$. This is still true at the surface of the sphere when $f = r$, so that the attraction at the surface = $\frac{4\pi r d}{3}$; which expression, with the help of what is proved in (12), enables us to compare the intensities of the attractions of homogeneous spheres, at all distances from the centre, without or within the surfaces.

Cor. 1. A shell of homogeneous matter contained between two concentric spherical surfaces, will attract a particle placed without it, with the same force as if all the matter of the shell were collected in its centre.

For the attractive force of such a shell is equal to the difference of the attractions of two concentric spheres of the same homogeneous matter with the shell.

Cor. 2. A sphere composed of concentric shells, that vary in their densities according to any law, will attract a particle placed without it, with the same force as if all the matter were collected in the centre.

For this having been proved of one shell (*Cor.* 1), it must be true of any number of shells.

If $\varphi(r)$ denote the density at the distance r from the centre, the quantity of matter in the sphere will be $= 4\pi \cdot \int \varphi(r) \cdot r^2 dr$; and the attraction on a particle without the sphere at the distance f from the centre = $\frac{4\pi \cdot \int \varphi(r) \cdot r^2 dr}{f^2}$. Attraction.

16. *Two spheres, each composed of concentric shells of variable density, attract one another with the same force as if all the matter of each were collected in its centre.*

For the attraction of a sphere A upon every particle of another sphere B will remain the same, if we suppose all the matter of A to be collected in its centre (15). But the attraction of any particles of matter placed in A's centre upon the sphere B is equal and opposite to the attraction of B, upon the same matter so placed; and again, the attraction of B upon all the particles placed in the centre of A, will remain unchanged, if we suppose the matter of B to be collected in its centre. Wherefore A attracts B with the same force as if the matter of each were collected in its centre.

17. *Supposing that the particles of matter attract with a force proportional to the distance, a body of any shape will attract a particle of matter placed anywhere with the same force, and in the same direction, as if all the matter of the body were collected in its centre of gravity.*

Suppose that the attracted particle is placed at P (fig. 9), and the centre of gravity of the attracting body at G; join PG, and let any plane pass through that line. Let L be a small part, or element of the body, and from L draw LK perpendicular to the plane passing through PG, and KF perpendicular to PG; join PL and PK. Put dm to denote the quantity of matter, or the mass of the element L; then its attractive force, urging the particle in the direction PL, is = PL × dm, which, by the resolution of forces, is equivalent to the two forces PK × dm and KL × dm; and again, the single force PK × dm is equivalent to the two forces FK × dm, and PF × dm = PG × dm + GF × dm. Wherefore, the attraction of the element L upon the particle at P is equivalent to these four separate forces, viz. PG × dm, GF × dm, FK × dm, KL × dm, which urge the particle P respectively in the directions PG, GF, FK, KL. But, from the nature of the centre of gravity, the sum of all the forces, KL × dm, that urge the particle P to one side of the plane passing through PG, is just equal to the sum of the forces that urge it to the other side of the same plane; and the sum of all the forces, FK × dm, that urge P to one side of the line PG, is just equal to the sum of the forces that urge it to the other side of the same line; and the sum of all the forces, GF × dm, that urge P towards the point G, is just equal to the sum of the forces that urge it from the same point. Wherefore all the preceding forces mutually destroy one another, excepting the forces PG × dm, the sum of which, when extended to all the elements of the attracting body, is = PG × mass of the body. Wherefore the whole attraction upon P is the same as if all the matter of the body were collected in its centre of gravity.

Cor. Supposing that the particles of matter attract with a force proportional to the distance, a homogeneous sphere will attract a particle placed anywhere, in the same manner as if all the matter of the sphere were collected in the centre.

For the centre of gravity of a homogeneous sphere is the same as the centre of its figure. This corollary is likewise true of a sphere composed of concentric shells of variable density; and it is easy to apply the demonstration of (16) to prove that, in this law of attraction, two spheres, each composed of concentric shells of variable density, will attract one another with the same force as if the matter of each were collected in its centre.

18. *To investigate what are the laws of attraction in re-*

Attraction. *gard to the distance according to which a shell of homogeneous matter, contained between two concentric spherical surfaces, will attract a particle placed without it, in the same manner as if all the matter of the shell were collected in the centre.*

It has been proved that this property actually belongs to homogeneous shells in the law of attraction which obtains in nature, and likewise when the particles of matter attract with a force proportional to the distance; but it is interesting to know whether it is confined to these two cases alone, or extends to other laws of attraction. This can only be discovered by a direct analysis.

Let $r = PC$ (fig. 10), the distance of the attracted point from the centre of the shell; $u = CA$, the radius of the inner surface of the shell; $f = PM$, the distance of P from any point in the surface. Having drawn the diameter AD through P, let AMD and AND be two great circles, making with one another an indefinitely small angle $MAN = dq$; and let two small circles BMG, *bmg*, indefinitely near one another, of which A and D are the poles, meet the former circles in M, N, *m*, *n*; and draw MS, NS to the centre of the circle BMG. Put θ for the measure of the arc AM; then $MS = u \sin.\theta$; $MN = dq.u \sin.\theta$; $Mm = ud\theta$; and the quadrilateral space $MNnm = u^2.dq.d\theta \sin.\theta$. We may suppose the thickness of the shell indefinitely small, since, if the property belong to an elementary shell indefinitely thin, it will be true of one of a determinate thickness, which can be resolved into such elements. Suppose the thickness of the shell to be $= du$; then the quantity of matter in the part standing upon the quadrilateral space $MNnm = u^2du.dq.d\theta \sin.\theta$. Let $\varphi(f)$ represent the direct attraction of a particle at M in the direction PM; then its attraction directed to the centre $C = \varphi(f) \times \frac{PS}{PM} = \frac{r-u\cos.\theta}{f} \times \varphi(f)$; and the attraction of the element of the shell in the same direction $= u^2du.dq.d\theta \sin.\theta \times \frac{r-u\cos.\theta}{f}.\varphi(f)$. This expression is proportional to dq, when θ and f remain constant; and therefore (denoting by π the circumference of the circle whose diameter is unit) the attraction of the whole zone contained between the small circles BMG, *bmg*, will be $= 2\pi.u^2du.d\theta \sin.\theta.\frac{r-u\cos.\theta}{f}.\varphi(f)$; and the attractive force of the whole shell will be

$$2\pi.u^2du\int d\theta \sin.\theta.\frac{r-u\cos.\theta}{f}.\varphi(f);$$

the fluent to be extended from $\theta = 0$ to $\theta = \pi$.

Again, the quantity of matter in the shell is $= 4\pi.u^2du$; and the attraction of this matter placed in the centre, at the distance r from P, is $= 4\pi.u^2du.\varphi(r)$.

If now we equate the attraction of the shell to the attraction of its matter placed in the centre, and leave out the factors common to both, we shall get

$$2\varphi(r) = \int d\theta \sin.\theta.\frac{r-u\cos.\theta}{f}.\varphi(f),$$

the limits of the integral being the same as before.

But $f^2 = r^2 - 2ru\cos.\theta + u^2$; then $d\theta \sin.\theta = \frac{fdf}{ru}$; also $r-u\cos.\theta = \frac{f^2+r^2-u^2}{2r}$; wherefore, by substitution, we get

$$4.r^2\varphi(r).u = \int(f^2+r^2-u^2).df.\varphi(f);$$

or, which is equivalent, $4.r^2\varphi(r).u =$

$$(f^2+r^2-u^2).\int df.\varphi(f) - 2\int fdf\int df.\varphi(f),$$

the limits of this integral being from $f = r-u$ to $f = r+u$, which correspond to $\theta = 0$ and $\theta = \pi$.

Now let $\int df.\varphi(f) = \Psi(f)$; and $\int fdf\int df.\varphi(f) =$ Attraction. $\int fdf.\Psi(f) = \Psi'(f)$; then, by taking the fluents between the proper limits, we get

$$4.r^2\varphi(r).u = 2r.[(r+u)\Psi(r+u) - (r-u)\Psi(r-u)] - 2[\Psi'(r+u) - \Psi'(r-u)].$$

If we develope the binomial functions in the last expression, all the even powers of u will disappear, and the odd powers only will remain; these last terms being all contained in this general formula,

$$\text{viz. } \frac{4}{1.2.3\ldots 2n+1}.\left\{r.\frac{d^{2n+1}r\Psi(r)}{dr^{2n+1}} - \frac{d^{2n+1}\Psi'(r)}{dr^{2n+1}}\right\}.u^{2n+1};$$

and, observing that $\frac{d.\Psi'(r)}{dr} = r\Psi(r)$, the same expression will become $\frac{4}{1.2.3\ldots.2n+1}$.

$$\left\{r.\frac{d^{2n+1}r\Psi(r)}{dr^{2n+1}} - \frac{d^{2n}r\Psi(r)}{dr^{2n}}\right\}.u^{2n+1};$$

which, again, is more simply expressed thus, viz.

$$\frac{4r^2}{1.2.3\ldots.2n+1}.\frac{d.\left\{\frac{1}{r}.\frac{d^{2n}r\Psi(r)}{dr^{2n}}\right\}}{dr}.u^{2n+1}.$$

Wherefore, by substituting the development instead of the functions, and then dividing by $4r^2u$, we get

$$\varphi(r) = \frac{d.\Psi(r)}{dr} + \frac{1}{1.2.3.}.\frac{d.\left\{\frac{1}{r}.\frac{d^2r\Psi(r)}{dr^2}\right\}}{dr}.u^2 + \frac{1}{1.2.3.4.5}.\frac{d.\left\{\frac{1}{r}.\frac{d^4r\Psi(r)}{dr^4}\right\}}{dr}.u^4 + \&c.$$

From the nature of the function $\Psi(r)$, we get $\varphi(r) = \frac{d.\Psi(r)}{dr}$; wherefore each of the remaining terms must be separately equal to nothing; hence

$$d.\left\{\frac{1}{r}.\frac{d^2r\Psi(r)}{dr^2}\right\} = 0;$$

from which we find $r\Psi(r) = \frac{1}{2}Ar^3 + A'r - A''$, A, A', A'' being arbitrary constant quantities; and this value of $r\Psi(r)$, it is plain, will likewise render all the succeeding terms of the development evanescent. Wherefore

$$\varphi(r) = \frac{d.\Psi(r)}{dr} = Ar + \frac{A''}{r^2}.$$

Thus the most general expression of the law of attraction, that possesses the property in question, is a combination of the two laws above mentioned, with each of which it coincides, according as we make the one or other of the constant quantities equal to nothing. We have, therefore, a direct proof that the law of nature is the only one which will make the attraction decrease as the distance increases, and in which a spherical shell, or a sphere, will attract in the same manner as if all the matter were collected in the centre.

Laplace has arrived at the same conclusion by a different process. (*Méc. Céleste*, livre ii. chap. 2, No. 12, Rem. part.)

ATTRACTION OF SPHEROIDS OF REVOLUTION.

19. *APBQ* (Plate CII. fig. 11) *and CMDN be two concentric ellipses similar to one another, and similarly situated, of which AB and CD are either the greater or less* Attraction of spheroids of revolution.

Attraction. *axes; and let PCQ be perpendicular to AB. Conceive the ellipses to revolve about PQ, so as to describe an indefinitely small angle; then, supposing the law of attraction to be inversely proportional to the square of the distance, the thin solid of homogeneous matter described by the ellipse APBQ will attract a particle placed at P, in a direction perpendicular to any plane passing through PQ, with the same force that the thin solid of the same matter described by the ellipse CMDN, will attract a particle placed at C perpendicularly to the same plane.*

From C draw CM, CN, making equal angles with CD, and PR, PT respectively parallel to CM, CN; and let C*m*, C*n*, P*r*, P*t*, be drawn in the same manner, and indefinitely near the former lines. While the ellipses revolve about PQ, the small sectors will describe pyramids that have their vertices at C and P. It is manifest that the pyramids so described are similar; for their angels at C and P in the planes of the ellipses are equal; and their other angles, described by revolving about PQ, are likewise equal, because the sectors are equally inclined to that axis. Wherefore the direct attractions of all the small pyramids upon the particles P and C are proportional to the lengths PR, PT, CM, CN (7); and consequently the forces that urge the particles P and C in a direction at right angles to any plane passing through PQ are proportional to the perpendiculars let fall upon that plane from R, T, M, N. But because PR, PT, CM, CN are equally inclined to PQ, they will make equal angles with any plane passing through PQ; wherefore the perpendiculars drawn to the plane from R, T, M, N, will be respectively proportional to PR, PT, CM, CN. But CM + CN = PR + PT (6); wherefore the sum of the perpendiculars drawn to the plane from M and N will be equal to the sum of the perpendiculars drawn to it from R and T. Consequently the force of the pyramids PR and PT, which urges the particle P at right angles to the plane, is equal to the force of the pyramids CM and CN, which urges the particle C in a parallel direction. The same thing is true of all the small pyramids that make up the thin solids described by the ellipses APBQ and CMDN; and it is therefore true of the whole solids.

It is to be observed that when the pyramids PR and PT fall on opposite sides of PQ, it is the difference of their attractions which is equal to the sum of the attractions of CM and CN; and it is the difference of the perpendiculars let fall from T and R on opposite sides of the plane, which is equal to the sum of the perpendiculars let fall from M and N.

20. *Let APBQ be a spheroid of revolution, PQ the axis of revolution, and ACB a plane through the centre perpendicular to PQ* (Plate CII. fig. 12). *If D be a particle in the surface of the spheroid, and DL perpendicular to the plane ACB; then the attraction of a spheroid on a particle placed at the pole P, will be to the force with which a particle placed at D is attracted in the direction DL, as PC is to DL.*

Through D draw a plane parallel to the plane ACB, and let the plane so drawn cut the axis PQ in F; draw the straight line DFE to terminate in the spheroid, and describe another spheroid through F, having the same centre with the spheroid APBQ, and similar to it, and similarly situated. Conceive an indefinitely great number of planes, making indefinitely small angles with one another, to be drawn through DE, so as to divide the two spheroids into an indefinitely great number of thin solids or slices; then the sections which every one of the planes make with the spheroids will be similar ellipses, having the same centre (5); and it is manifest that a straight line drawn through F at right angles to DE, in any one of the planes, will pass through the centre of the two ellipses contained in it, and will coincide with an axis of each. Wherefore the force with which every one of the slices or elements of the spheroid APBQ attracts a particle placed at D in the direction DL, is equal to the force with which the corresponding slice or element of the spheroid GFHK attracts a particle placed at F in the direction FC (19). Wherefore, the whole attraction of the spheroid APBQ upon a particle at D, in the direction DL, is equal to the whole attraction of the spheroid GFHK upon a particle at F. But the attractions of the spheroids APBQ and GFHK upon particles placed at P and F, are to one another as PC to FC (8). Wherefore, the attraction of the spheroid APBQ upon a particle at P, is to the force with which the same spheroid attracts a particle at D, in the direction DL, as PC is to FC or DL. Attraction.

21. *Let APBQ be a spheroid of revolution, and PQ the axis of revolution as before. If D be a particle in the surface, ADPB* (fig. 13) *a section through D, and the axis PQ and DL perpendicular to PQ; the attraction of the spheroid upon a particle at A will be to the force with which a particle at D is attracted, in the direction DL, as AC is to DL.*

Through D draw a plane perpendicular to AB, which cuts the section ADB in the straight line DFE; and let a spheroid FGHK be described through F, having the same centre with the spheroid APBQ, and similar to it, and similarly situated. Then, conceiving the two spheroids to be divided into an indefinitely great number of thin slices by planes passing through DE, the force with which every slice or element of the spheroid APBQ attracts a particle at D in the direction DL, will be equal to the force with which the corresponding slice or element of the spheroid FGHK attracts a particle at F (19). But the attractions of the spheroids APBQ and FGHK upon particles placed at A and F are to one another as AC to CF (8). Wherefore, the attraction of the spheroid APBQ upon a particle at A is to the force with which the same spheroid attracts a particle at D, in the direction DL, as AC to FC or DL.

The two last propositions will enable us to find both the direction and the intensity of the attraction of a homogeneous spheroid of revolution upon a particle placed anywhere on the surface, when we have ascertained the attractive forces at the poles and at the circumference of the circular section made by a plane through the centre perpendicular to the axis. For the whole attraction at any point is the compound force arising from the attractions perpendicular to the axis, and parallel to it. The next object of our research is, therefore, to determine the two forces above mentioned, viz. the attraction at the poles, and at the circular section equally distant from both poles.

22. *Let ABD be an indefinitely slender pyramid, of which the base BD is perpendicular to the edge AD* (fig. 14); *let B=base BD, and f=length AD; then* $\frac{B}{f}$ *= the attraction of the whole matter of the pyramid upon a particle placed at the vertex A.*

Let AM $= x$, then the section MN parallel to the base BD $= \frac{B.x^2}{f^2}$, and MP = element of the prism $= \frac{B.x^2dx}{f^2}$, and the attraction of the element upon a particle placed at A $= \frac{MP}{AM^2} = \frac{B.dx}{f^2}$, the fluent of which is $= \frac{Bx}{f^2}$ = attraction of the pyramid AM upon a particle at A. And, when $x = f$, this becomes $= \frac{B}{f}$ = attraction of the pyramid AD upon a particle placed at A.

Attraction. 23. *To investigate the attraction of a homogeneous spheroid of revolution upon a particle placed at the pole.*

Let P (fig. 15) be the pole, PCQ the axis of revolution, and APBQ a section of the spheroid by a plane passing through PQ, and any point M, in the surface; draw PM, Pm indefinitely near PM, and Mm perpendicular to Pm. Conceive the plane PMQ to revolve about PQ, so as to describe the indefinitely small angle BCO; then the small triangle MPm will describe a slender pyramid, having its vertex at P, and of which the base is a rectangle, contained by Mm and RT; for the point M moving parallel to R, it will describe a line equal and parallel to that described by R, namely, to RT.

Let PM $= f$, and the angle KPM, which PM makes with a perpendicular to the axis, $= \theta$, and the indefinitely small angle BCO $= d\varphi$. Then $Mm = f d\theta$, RT $=$ CR $\times d\varphi = f \cos.\theta \,.\, d\varphi$, and B, the base of the slender pyramid described by the triangle MPm, $= d\varphi \,.\, d\theta \cos.\theta \,.\, f^2$; wherefore the direct attraction of the pyramid on a particle at P $= \frac{B}{f}(22) = d\varphi \,.\, d\theta \cos.\theta \,.\, f$, and the elementary attraction of the spheroid in the direction PC $=$ direct attraction of the pyramid $\times \frac{PS}{PM} = d\varphi \,.\, d\theta \cos.\theta \sin.\theta \,.\, f$.

Again, let MR $= x$, CR $= y$, PC $= k$, AC $= k'$; then $y = f\cos.\theta$, $x = k - f\sin.\theta$: if we substitute these values in the equation of the solid (Def. 1) we get

$$\frac{(k - f\sin.\theta)^2}{k^2} + \frac{f^2\cos.^2\theta}{k'^2} = 1; \text{ whence}$$

$$f = \frac{2k'^2k}{k^2} \cdot \frac{\sin.\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta}.$$

By substituting the value of f just found in the preceding expression of the elementary attraction of the spheroid, it will become

$$\frac{2k'^2k}{k^2} d\varphi \cdot \frac{d\theta \cos.\theta \,.\, \sin.^2\theta}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta};$$

which must be integrated from $\varphi = 0$ to $\varphi = 2\pi$, and from $\theta = 0$ to $\theta = \frac{\pi}{2}$, π denoting always the half-circumference when radius is unit.

In an oblate spheroid, k is less than k': put $k'^2 - k^2 = k^2 \,.\, e^2$, and $z = \sin.\theta$; then the element of the attractive force will become, by substitution,

$$\frac{2k'^2k}{k^2} d\varphi \cdot \frac{z^2dz}{1 + e^2z^2} = \frac{2k'^2k \,.\, d\varphi}{k^2e^3} \cdot \left\{ edz - \frac{edz}{1 + e^2z^2} \right\};$$

and by integrating from $z = 0$ to $z = 1$, we get

$$\frac{2k'^2k \,.\, d\varphi}{k^2e^3} \cdot [e - \text{arc. tan. } e]$$

for the force with which the matter between the planes PBQ and POQ urges the particle P to the centre. Wherefore the whole attractive force of the spheroid upon a particle at P is $=$

$$\frac{4\pi \,.\, k'^2k}{k^2e^3} \cdot [e - \text{arc. tan. } e].$$

And because $\frac{4\pi \,.\, k'^2k}{3} =$ mass of the spheroid $= M$, we get the measure of the attraction of the oblate spheroid upon a particle placed at the pole equal to

$$k \cdot \frac{3M}{k^3e^3} \cdot [e - \text{arc. tan. } e].$$

In an oblong spheroid, k is greater than k'; put $k^2 - k'^2 = k^2e^2$, then the element of the attractive force will become, by substitution, Attraction.

$$\frac{2k'^2k}{k^2} d\varphi \cdot \frac{z^2dz}{1 - e^2z^2} = \frac{2k'^2k \,.\, d\varphi}{k^2e^3} \left\{ \frac{edz}{1 - e^2z^2} - edz \right\};$$

whence, by proceeding as before, we get the measure of the attractive force of the oblong spheroid on a particle placed at the pole equal to

$$k \cdot \frac{3M}{k^3e^3} \cdot \left\{ \frac{1}{2} \text{ hyp. log. } \frac{1 + e}{1 - e} - e \right\}$$

Cor. In an oblate spheroid differing little from a sphere, e^2 will be a very small fraction, of which we may reject the higher powers. When this is done, the preceding expression of the polar attraction, viz.

$$\frac{4\pi \,.\, kk'^2}{k^2e^3} \cdot (e - \text{arc. tan. } e),$$

will be $= 4\pi k \,.\, (1 + e^2) \,.\, (\frac{1}{3} - \frac{1}{5}e^2) = \frac{4\pi k}{3}\left(1 + \frac{2}{5}e^2\right)$.

And, if $k' = k + r = k\sqrt{1 + e^2}$ be the radius of the equator, then $2\frac{r}{k} = e^2$, so that the attraction at the pole will be

$$\frac{4\pi k}{3} \cdot \left(1 + \frac{4}{5} \cdot \frac{r}{k}\right).$$

24. *To investigate the attraction of a homogeneous spheroid of revolution on a particle placed in the circumference of the circular section made by a plane through the centre, at right angles to the axis of revolution.*

Let P (Plate CII. fig. 16) be the pole, PC the axis of revolution, A a point in the circular section AOB, made by a plane through the centre perpendicular to PC. Let M be any point in the surface of the spheroid, AMO a section through A and M by a plane perpendicular to to AOB, Am a line in that plane indefinitely near AM, and Mm perpendicular to Am, MR perpendicular to AO, and RS to AB. Conceive the plane AMO to revolve about A, so as to describe an indefinitely small angle OAQ; then the triangle AMm will describe a slender pyramid, having its vertex at A, and of which the base is equal to a rectangle contained by Mm and RT; for the point M moving parallel to the point R, it will describe a line equal to that described by R, namely, to RT.

Let AM $= f$, the angle MAR $= \theta$, and the angle OAQ $= d\varphi$; then $Mm = f d\theta$, and TR $=$ AR $\times d\varphi = f\cos.\theta \,.\, d\varphi$. Wherefore B $=$ base of the pyramid described by MAm $= d\varphi \,.\, d\theta \cos.\theta \,.\, f^2$, and the direct attraction of the pyramid in the direction AM $= \frac{B}{f}(22) = d\varphi \,.\, d\theta \cos.\theta \,.\, f$. Wherefore the elementary attraction of the spheroid in the direction AC $=$ direct attraction of the pyramid $\times \frac{AR}{AM} \times \frac{AS}{AR}$ $= d\varphi \cos.\varphi \,.\, d\theta \cos.^2\theta \,.\, f$.

Again, let MR $= x$, RS $= y$, CS $= z$, CP $= k$, and AC $= k'$; then (Def. 1)

$$\frac{x^2}{k^2} + \frac{y^2 + z^2}{k'^2} = 1.$$

But $x = f \sin.\theta$, $y =$ AR $\,.\, \sin.\varphi = f\cos.\theta \sin.\varphi$, and $z = k' - f\cos.\theta\cos.\varphi$; wherefore, by substitution, we get

$$\frac{f^2\sin.^2\theta}{k^2} + \frac{f^2\cos.^2\theta\sin.^2\varphi}{k'^2} + \frac{(k' - f\cos.\theta\cos.\varphi)^2}{k'^2} = 1.$$

From this equation we get

$$f = 2k' \cdot \frac{\cos.\theta\cos.\varphi}{\cos.^2\theta + \frac{k'^2}{k^2}\sin.^2\theta}.$$

Let this value of f be substituted in the expression of the elementary attraction of the spheroid before found, and it will become

Attraction.

$$2k' \cdot d\varphi \cos.^2 \varphi \cdot \frac{d\theta \cos.^3 \theta}{\cos.^2 \theta + \frac{k^2}{k^2} \sin.^2 \theta};$$

which expression, when integrated from $\varphi = 0$ to $\varphi = \pi$, and from $\theta = 0$ to $\theta = \frac{1}{2}\pi$, will give the attraction of half the spheroid: and the double of it, viz.

$$4k' \cdot d\varphi \cos.^2 \varphi \cdot \frac{d\theta \cos.^3 \theta}{\cos.^2 \theta + \frac{k^2}{k^2} \sin.^2 \theta},$$

being integrated between the same limits, will give the whole attraction of the spheroid.

In the oblate spheroid, k is less than k': Let $k'^2 - k^2 = k^2e^2$, and $z = \sin. \theta$; and, by substitution, the element of the attractive force will become

$$4k' \cdot d\varphi \cos.^2 \varphi \cdot \frac{dz(1 - z^2)}{1 + e^2z^2} =$$

$$4k' \cdot d\varphi \cdot \cos.^2 \varphi \cdot \frac{1 + e^2}{e^3} \cdot \left\{ \frac{edz}{1 + e^2z^2} - \frac{edz}{1 + e^2} \right\}.$$

And by integrating from $z = 0$ to $z = 1$, we get

$$4k' \cdot d\varphi \cos. \varphi \cdot \frac{1 + e^2}{e^3} \cdot \left\{ \text{arc. tan. } e - \frac{e}{1 + e^2} \right\};$$

for the force with which the matter between the sections that contain the angle OAQ attracts the particle A to the centre. But $\int d\varphi \cos.^2 \varphi = \int \frac{d\varphi}{2} \cdot (1 + \cos. 2\varphi)$ $= \frac{\varphi}{2} + \frac{1}{4} \sin. 2\varphi$; the value of which, between the limits $\varphi = 0$, and $\varphi = \pi$, is $= \frac{\pi}{2}$: wherefore the attraction of the spheroid on a particle at A is equal to

$$2\pi \cdot k' \frac{1 + e^2}{e^3} \cdot \left\{ \text{arc. tan. } e - \frac{e}{1 + e^2} \right\}.$$

Because $\frac{4\pi \cdot k'^2k}{3} = \frac{4\pi \cdot k^3 \cdot (1 + e^2)}{3} = \text{M}$; we get $2\pi \cdot (1 + e^2) = \frac{3\,\text{M}}{2k^3}$: wherefore the measure of the attractive force of the oblate spheroid on a particle placed anywhere in the circumference of the circular section made by a plane through the centre at right angles to the axis, is equal to

$$k \cdot \frac{3\,\text{M}}{2k^3 \cdot e^3} \cdot \left\{ \text{arc. tan. } e - \frac{e}{1 + e^2} \right\}.$$

In the oblong spheroid, k is greater than k'; put $k'^2 - k^2 = k^2 \cdot e^2$, then the element of the attractive force will become, by substitution,

$$4k' \cdot d\varphi \cos.^2 \varphi \cdot \frac{dz(1 - z^2)}{1 - e^2z^2} = 4k' \cdot d\varphi \cos.^2 \varphi \cdot \frac{1 - e^2}{e^3} \cdot \left\{ \frac{edz}{1 - e^2} - \frac{edz}{1 - e^2z^2} \right\}:$$

whence, by proceeding as before, we get the measure of the attractive force of the oblong spheroid upon a particle placed anywhere in the circumference of the circular section made by a plane through the centre at right angles to the axis, equal to

$$k' \cdot \frac{3\,\text{M}}{2k^3 \cdot e^3} \cdot \left\{ \frac{e}{1 - e^2} - \frac{1}{2} \text{ hyp. log. } \frac{1 + e}{1 - e} \right\}.$$

Cor. In an oblate spheroid, differing little from a sphere, the higher powers of e^2 may be neglected. The expression of the attractive force at the equator, viz.

$$2\pi \cdot k' \cdot \frac{1 + e^2}{e^3} \cdot \left\{ \text{arc. tan. } e - \frac{e}{1 + e^2} \right\},$$

will then become

$$2\pi \cdot k' \cdot (1 + e^2) \left(\frac{2}{3} - \frac{4}{5} e^2 \right) = \frac{4\pi k'}{3} \cdot (1 - \frac{1}{5} e^2).$$

And if k', the radius of the equator, $= k + r$; then $\frac{2r}{k} = e^2$ (23, *Cor.*); and the attraction at the equator will be equal to

$$\frac{4\pi k}{3} \cdot \left(1 + \frac{r}{k}\right) \cdot \left(1 - \frac{2}{5} \cdot \frac{r}{k}\right) = \frac{4\pi k}{3} \cdot \left(1 + \frac{3}{5} \cdot \frac{r}{k}\right).$$

25. *An oblate spheroid of revolution being given, it is required to find the measures of the attractive forces that urge a particle placed anywhere in the surface, in a direction perpendicular to the axis, and in a direction parallel to it.*

Let k and k' be the semiaxes of the ellipse, by the revolution of which the spheroid is described, k being the axis about which it revolves; and let b be the perpendicular distance of the particle from the axis, and a its distance from the plane, drawn through the centre at right angles to the axis: then, from what was proved in (20) and (21), the attractions sought will be found by multiplying the attractions at the pole, and at the circular section equally distant from both poles, by $\frac{a}{k}$ and $\frac{b}{k'}$.

Thus we get the attraction in the direction of a equal to

$$a \times \frac{3\,\text{M}}{k \cdot e^3} \cdot [e - \text{arc. tan. } e],$$

and the attraction in the direction of b equal to

$$b \times \frac{3\,\text{M}}{2k^3 \cdot e^3} \cdot \left\{ \text{arc. tan. } e - \frac{e}{1 + e^2} \right\}.$$

The same formulæ likewise serve for finding the attractions upon a particle placed anywhere within the spheroid. For the attraction upon a particle within the spheroid is equal to the attraction of a similar concentric spheroid, which contains the particle in its surface (9); and it is evident that the co-efficients which multiply a and b in the above expressions depend only upon the proportion of k and k', and they are therefore the same for all similar spheroids.

If we denote by A and B the co-efficients of a and b in the expressions of the attractive force found above, the whole attraction of the spheroid, which is compounded of the forces $a \cdot \text{A}$ and $b \cdot \text{B}$, will be $= \sqrt{a^2\text{A}^2 + b^2\text{B}^2}$. And if Ψ denote the angle which the direction of this force makes with a, or with the axis of the spheroid; then $\tan. \Psi = \frac{b \cdot \text{B}}{a \cdot \text{A}}$.

Cor. In the very same manner we may determine the attractions of an oblong spheroid of revolution, upon a point in the surface, or within the solid.

26. *If k, k', k', the semiaxes of a homogeneous ellipsoid, be related to h, h', h'', those of another ellipsoid of the same matter, so that $k'^2 - k^2 = h'^2 - h^2$ and $k''^2 - k^2 = h''^2 - h^2$, the attractions perpendicular to the planes of the principal sections, which the first ellipsoid* (Plate CII. fig. 17) *exerts upon a point determined by the co-ordinates $h \sin. m$, $h' \cos. m \sin. n$, $h'' \cos. m \cos. n$, respectively parallel to h, h', h'', will be to the attractions which the second ellipsoid exerts upon a point determined by the co-ordinates $k \sin. m$, $k' \cos. m \sin. n$, $k'' \cos. m \cos. n$, respectively parallel to h, h', h'', in the direct proportion of the areas of the principal sections to which the attractions are perpendicular.*

This proposition is an extension to all elliptical spheroids of what was proved of the sphere in (13). It is here enunciated of the ellipsoid, because the demonstration is not more difficult for that solid than for spheroids of revolution.

Let ABDM be an ellipsoid, the semiaxes of which are $\text{BC} = k$, $\text{EC} = k'$, and $\text{AC} = k''$; and *abdm* another ellipsoid, of which the semiaxes are $bc = h$, $ec = h'$, and $ac = h''$; those quantities being so related that $k'^2 - k^2 = h'^2 - h^2$, and $k''^2 - k^2 = h''^2 - h^2$. Also, let G be a point about the ellipsoid ABDM, so determined that GH, parallel to BC, $= h \sin. m$; HK, parallel to CE, $= h' \cos. m$

Attraction. sin. n; and CK $= h''$ cos. m cos. n; and let g be a point about the ellipsoid $abdm$, so determined that gh, parallel to bc, $= k$ sin. m; hk, parallel to ce, $= k'$ cos. m sin. n; and $ck = k''$ cos. m cos. n. Then the force with which the ellipsoid ABDM attracts a particle placed at G in the direction GH, will be to the force with which the ellipsoid $abdm$ attracts a particle placed at g in the direction gh, as the area of the section AEDM to the area of the section $aedm$, or as $k'\,k''$ to $h'\,h''$.

Let RP $= k$ sin. θ; PO $= k'$ cos. θ sin. φ; and CO $= k''$ cos. θ cos. φ; which suppositions are allowable, because they satisfy the equation of the ellipsoid (Def. 1), whatever be the angles θ and φ. Draw CPM through the centre, and CN indefinitely near it; then CP $=$ cos. $\theta \sqrt{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}$; and when cos. $\theta = 1$, CM $= \sqrt{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}$; wherefore $\frac{\text{CP}}{\text{CM}} =$ cos. θ.

Let the angle DCM $= \Psi$; then tan. $\Psi = \frac{\text{PO}}{\text{CO}} = \frac{k'}{k''}$ tan. φ; and, by taking the fluxions, $\frac{d\Psi}{\cos.^2 \Psi} = \frac{k'}{k''} \cdot \frac{d\varphi}{\cos.^2 \varphi}$; but

$$\frac{1}{\cos.^2 \Psi} = 1 + \tan.^2 \Psi = \frac{k'^2 \sin.^2 \varphi + k''^2 \cos.^2 \varphi}{k''^2 \cos.^2 \varphi} = \frac{\text{CM}^2}{k''^2 \cos.^2 \varphi};$$

wherefore $d\Psi$. CM^2 $=$ twice the sector MCN $= k'\,k''$. $d\varphi$.

And, in like manner, in the other ellipsoid, if $rp = h$ sin. θ; $po = h'$ cos. θ sin. φ; and $co = h''$ cos. θ cos. φ: then $\frac{cp}{cm}$ $=$ cos. θ, and twice the sector $mcn = h'\,h''\,d\varphi$.

It is plain, from what has been shown, that, when θ varies and φ remains constant in the expressions of the co-ordinates, the points P and p will move along CM and cm, so that, in every position, $\frac{\text{PC}}{\text{MC}} = \frac{pc}{mc}$. Let Q and q be indefinitely near P and p; and through P and Q draw lines parallel to MN, and through p and q draw lines parallel to mn. Let S denote the quadrilateral contained between the parallels drawn through P and Q, and S$'$ that contained between the lines drawn through p and q: Then $\frac{\text{S}}{\text{MCN}} = \frac{\text{QC}^2 - \text{PC}^2}{\text{MC}^2}$, and $\frac{\text{S}'}{\text{MCN}} = \frac{qc^2 - pc^2}{mc^2}$; wherefore, since $\frac{\text{PC}}{\text{MC}} = \frac{pc}{mc}$, and $\frac{\text{QC}}{\text{MC}} = \frac{qc}{mc}$, it is manifest that $\frac{\text{S}}{\text{S}'} = \frac{\text{MCN}}{mcn} = \frac{k'\,k''}{h'\,h''}$.

Upon the quadrilaterals S and S$'$ let upright prisms RS and rs be erected, and be prolonged to meet the surfaces of the spheroids; join GR, GS, gr, gs. Then,

$$\text{GR}^2 = (h \sin. m - k \sin. \theta)^2 + (h' \cos. m \sin. n - k' \cos. \theta \sin. \varphi)^2 + (h'' \cos. m \cos. n - k'' \cos. \theta \cos. \varphi)^2;$$

$$gr^2 = (h \sin. m - k \sin. \theta)^2 + (k' \cos. m \sin. n - h' \cos. \theta \sin. \varphi)^2 + (k'' \cos. m \cos. n - h'' \cos. \theta \cos. \varphi)^2;$$

And, by expanding these expressions, we get

$$\text{GR}^2 = [(h^2 + (h'^2 - h^2) \cos.^2 m \sin.^2 n + (h''^2 - h^2) \cos.^2 m \cos.^2 n) + (k^2 + (h'^2 - k^2) \cos.^2 \theta \sin.^2 \varphi + (h''^2 - k^2) \cos.^2 \theta \cos.^2 \varphi) - 2 (hk \sin. m \sin. \theta + h'\,k' \cos. m \cos. \theta \sin. n \sin. \varphi + h''\,k'' \cos. m \cos. \theta \cos. n \cos. \varphi)];$$

and $gr^2 = [(k^2 + (k'^2 - k^2) \cos.^2 m \sin.^2 n + (k''^2 - k^2) \cos.^2 m \cos.^2 n) + (h^2 + (h'^2 - h^2) \cos.^2 \theta \sin.^2 \varphi + (h''^2 - h^2) \cos.^2 \theta \cos.^2 \varphi) - 2 (hk \sin. m \sin. \theta + h'\,k' \cos. m \cos. \theta \sin. n \sin. \varphi + h''\,k'' \cos. m \cos. \theta \cos. n \cos. \varphi)]$.

These expressions are equal, because $k'^2 - k^2 = h'^2 - h^2$, and $k''^2 - k^2 = h''^2 - h^2$; wherefore RG $= rg = f$. And, in like manner, it is shown, that GS $= gs = f'$.

Now, the attraction of the prism RS urging a particle at G in the direction GH, is equal to S $\times \left\{\frac{1}{f} - \frac{1}{f'}\right\}$ (10); and the attraction of the prism rs urging a particle at g in the direction gh, is $= \text{S}' \times \left\{\frac{1}{f} - \frac{1}{f'}\right\}$: wherefore these attractions are to one another as S to S$'$, or as $k'\,k''$ to $h'\,h''$. The same thing may be proved of all the elementary prisms that make up the two portions of the ellipsoids contained between the planes BCM, BCN, and bcm, bcn; wherefore those portions attract particles placed at G and g, with forces proportional to $k'\,k''$ and $h'\,h''$. But the two ellipsoids may be divided into an equal number of such portions; wherefore the ellipsoids attract particles placed at G and g, in the directions GH and gh, with forces proportional to $k'\,k''$ and $h'\,h''$, or to the sections AMDE and $amde$.

Cor. 1. This proposition is true when the law of attraction is expressed by any function of the distance. The demonstration is the same as in the corollary of (13).

Cor. 2. If the two ellipsoids be so placed that their centres, and the planes of their principal sections, shall coincide, the surface of the one will be entirely within the other. Also the point which one ellipsoid attracts will be in the surface of the other, as is plain from the expressions of the co-ordinates. And hence the attraction of one ellipsoid upon a point without the surface is made to depend upon the attraction of another ellipsoid upon a point within the surface.

Cor. 3. When the ellipsoids become spheroids of revolution, the two principal sections through the axis of revolution become equal, and will be represented by any two sections whatever passing through the axis at right angles to one another. But, in this case, the attractions of the spheroids on the points may be reduced to two, one acting perpendicular to the axis, and one parallel to it; and it is plain that these attractions will be to one another as the areas of the sections perpendicular to their directions.

27. *To find the attraction of an oblate spheroid upon a particle placed without the surface.*

Let k' be the radius of the equator, and k the axis of revolution; and let a be the perpendicular distance of the point without the spheroid from the plane of the equator, and b its distance from the axis. In the first place, it is necessary to determine the semiaxis of another oblate spheroid that shall contain the given point in its surface, and such, that it shall have the same centre, and its equator in the same plane, as the given spheroid; and likewise the difference of the squares of its semiaxes equal to the difference of the squares of the semiaxes of the given spheroid. Let h' denote the radius of the equator, and h the semiaxis of the required spheroid; then, because the attracted point is to be in the surface of the solid, we have $\frac{a^2}{h^2} + \frac{b^2}{h'^2} = 1$; and, because $h'^2 - h^2 = k'^2 - k^2 = \varepsilon^2$, we get

$$\frac{a^2}{h^2} + \frac{b^2}{h'^2 - \varepsilon^2} = 1:$$

Whence,

$$2h^2 = a^2 + b^2 - \varepsilon^2 + \sqrt{(a^2 + b^2 - \varepsilon^2)^2 + 4a^2 \varepsilon^2};$$

and when h is determined, then $h' = \sqrt{h^2 + \varepsilon^2}$.

In consequence of the equation $\frac{a^2}{h^2} + \frac{b^2}{h'^2} = 1$, we may suppose $a = h$ sin. m, and $b = h'$ cos. m; let $a' = k$ sin. m, and $b' = k$ cos. m; or $a' = \frac{k}{h} a$, and $b' = \frac{k'}{h} \times b$: then the point determined by the co-ordinates a' and b' will be in the surface of the given spheroid, and consequently

Attraction. it will be within the surface of the other spheroid. Let M′ denote the mass of the spheroid of which the axis is h; and let $e^2 = \frac{h^2 - k^2}{h^2} = \frac{k'^2 - k^2}{k'^2}$: then (25) the attractions of this spheroid upon the point within its surface, determined by the co-ordinates a and b, are these, viz.

That perpendicular to the equator, equal to

$$a' \times \frac{3M}{h^3 e^3} \cdot [e' - \text{arc. tan. } e'];$$

and that perpendicular to the axis, equal to

$$b' \times \frac{3M'}{2h^3 e^3} \cdot \left\{ \text{arc. tan. } e' - \frac{e'}{1 + e'^2} \right\}.$$

But (26, Cor. 3) the attractions of the given spheroid, whose semiaxes are k and k', upon the point without its surface determined by the co-ordinates a and b, will be found by multiplying the preceding expressions respectively by $\frac{k^2}{k'^2}$ and $\frac{kk'}{kk'}$. Let M be the mass of the given spheroid; then $\frac{M}{M'} = \frac{k'^2 k}{k'^2 h}$; consequently $\frac{k^2}{k'^2} = \frac{M}{M'} \cdot \frac{h}{k} = \frac{M}{M'} \cdot \frac{a}{a'}$; and $\frac{kk'}{kk'} = \frac{M}{M'} \cdot \frac{k'}{k} = \frac{M}{M'} \cdot \frac{b}{b'}$: wherefore the attractions of the given oblate spheroid upon a point without the surface determined by the co-ordinates a and b, are as follows, viz.

The attraction perpendicular to the equator, equal to

$$a \times \frac{3M}{h^3 e^3} [e' - \text{arc. tan. } e'];$$

and that perpendicular to the axis, equal to

$$b \times \frac{3M}{2h^3 e^3} \left\{ \text{arc. tan. } e' - \frac{e'}{1 + e'^2} \right\}.$$

Cor. In the very same manner we may determine the attractions of an oblong spheroid of revolution upon a point without the surface.

ATTRACTIONS OF ELLIPSOIDS.

Attractions of ellipsoids.

28. *Let AMBN be one of the principal sections of an ellipsoid, C the centre, AB and MN the axes, D a point in the periphery of the section, and DO perpendicular to MN* (Plate CII. fig. 18); *the attraction of the ellipsoid upon a particle placed at the pole A is to the force with which a particle placed at D is attracted in the direction DO, as AC to DO.*

Draw DFG perpendicular to AB, and through F describe an ellipsoid similar to the given ellipsoid, and similarly situated, and having the same centre. Conceive an indefinitely great number of planes, making indefinitely small angles with one another, to be drawn through DG, so as to divide the two ellipsoids into an indefinitely great number of thin solids or slices; then the sections of the ellipsoids made by every one of the planes will be similar and concentric ellipses, each of them having an axis perpendicular to DG (5). Wherefore the attractions of the elements of the ellipsoid FHKL, upon a particle at F, are respectively equal to the attractions of the elements of the ellipsoid AMBN, upon a particle at D in the direction DO (19). Wherefore the whole attraction of the ellipsoid FHKL, upon a particle at F, is equal to the attraction of the ellipsoid AMBN, upon a particle at D, in the direction DO. But the attractions of the ellipsoids AMBN and FHKL, upon particles at A and F, are to one another as AC to CF (8). Wherefore the attraction of the ellipsoid AMBN, upon a particle at the pole A, is to the force with which it attracts a particle at D in the direction DO, as AC to DO.

29. *The attractions of ellipsoids upon particles placed in the surface, urging them in directions perpendicular to any of the principal sections, are proportional to the distances of the particles from that section.* Attraction.

Let AMBN be one of the principal sections of an ellipsoid, C the centre, AB and MN the axes of the section, and P a point in the surface of the solid: the attraction of the ellipsoid upon a particle at the pole A (Pl. CII. fig. 19) is to the force with which a particle at P is attracted in a direction parallel to AB, as the semiaxis AC is to the distance of P from the principal section perpendicular to AC.

Draw PDQ perpendicular to the section AMBN, and let it meet the surface again in Q; through D describe an ellipsoid similar to AMBN, similarly situated, and having the same centre; and through P draw a section SPRQ perpendicular to AB. As before, divide the solids into an indefinitely great number of thin slices, by planes drawn through PQ: the sections made by every one of those planes will be similar, and concentric ellipses having an axis of each perpendicular to PQ (5). Wherefore the attractions of the elements of the ellipsoid AMBN, upon a particle at P, in a direction perpendicular to the plane PRQS, are respectively equal to the attractions of the elements of the ellipsoid FHKL upon a particle at D, in a direction perpendicular to the same plane (19). Wherefore the attraction of the ellipsoid AMBN, upon a particle at P, in a direction parallel to the axis AB, is equal to the attraction of the ellipsoid FHKL upon a particle at D in the same direction. But the ellipsoids AMBN and FHKL being similar, their attractions upon particles at A and F are to one another as AC to CF (8); and the attraction of the ellipsoid FHKL, upon a particle at the pole F, is to its attraction upon a particle at D, in a direction parallel to AC, as FC to CN (28). Wherefore (*ex æquali*) the attraction of the ellipsoid AMBN, upon a particle at the pole A, is to the force with which it attracts a particle at P, in the direction AC, as AC to CN.

This proposition will enable us to find the attractions of an ellipsoid on all points on the surface, or within the solid, when the attractions at the poles are determined.

30. *To investigate the differential expressions of the attractions at the poles of an ellipsoid.*

Let APD be an ellipsoid; C the centre; AC, CE, and PC, the semiaxes; and PMB a section made by a plane through PC and any point M in the surface: draw PM (fig. 20) Pm indefinitely near PM, and Mm perpendicular to Pm; also MR perpendicular to the plane ADB, MS perpendicular to PC, and RH perpendicular to AD. Conceive the plane PCB to revolve about PC, so as to describe an indefinitely small angle BCO; and let PM $= f$; the angle KPM which PM makes with a perpendicular to the axis $= \theta$; and the angle DCB $= \varphi$: then, by proceeding as in (23), it will be found that the attraction of the small pyramid described by the triangle MPm, urging a particle at P to the centre of the ellipsoid, is $= d\varphi \cdot d\theta \cos. \theta \sin. \theta \cdot f$.

Again, let MR $= x$, HR $= y$, CH $= z$; also let PC $= k$, AC $= k'$, CE $= k''$; then $x = k - f \sin. \theta$; $y = f \cos. \theta \sin. \varphi$; $z = f \cos. \theta \cos. \varphi$; and if we substitute these values in the equation of the ellipsoid (Def. 2), we shall get

$$\frac{(k - f \sin. \theta)^2}{k^2} + \frac{f^2 \cos.^2 \theta \sin.^2 \varphi}{k'^2} + \frac{f^2 \cos.^2 \theta \cos.^2 \varphi}{k''^2} = 1$$

whence

$$f = \frac{k}{k^2} \cdot \frac{2 \sin. \theta}{\frac{\sin.^2 \theta}{k^2} + \frac{\cos.^2 \theta \sin.^2 \varphi}{k'^2} + \frac{\cos.^2 \theta \cos.^2 \varphi}{k''^2}}.$$

This is the value of f at the pole of k; and, by a like procedure, its values at the poles of k' and k'' may be found, viz.

Attraction

$$f = \frac{k'}{k'^2} \cdot \frac{2 \sin.\theta}{\frac{\sin.^2\theta}{k'^2} + \frac{\cos.^2\theta \sin.^2\varphi}{k^2} + \frac{\cos.^2\theta \cos.^2\varphi}{k''^2}},$$

$$f = \frac{k''}{k''^2} \cdot \frac{2 \sin.\theta}{\frac{\sin.^2\theta}{k''^2} + \frac{\cos.^2\theta \sin.^2\varphi}{k^2} + \frac{\cos.^2\theta \cos.^2\varphi}{k'^2}}.$$

Suppose that k is the least of the semiaxes; and let $k'^2 = \frac{k^2}{m}$, and $k''^2 = \frac{k^2}{n}$; then the values of f at the poles of k, k', k'', will be respectively

$$f = \frac{2k \sin.\theta}{\sin.^2\theta + m\cos.^2\theta \sin.^2\varphi + n\cos.^2\theta \cos.^2\varphi},$$

$$f = \frac{2k' \sin.\theta \times m}{m\sin.^2\theta + \cos.^2\theta \sin.^2\varphi + n\cos.^2\theta \cos.^2\varphi},$$

$$f = \frac{2k'' \sin.\theta \times n}{n\sin.^2\theta + \cos.^2\theta \sin.^2\varphi + m\cos.^2\theta \cos.^2\varphi}.$$

Now let A, A′, A″, denote the attractions of the spheroid upon particles placed at the poles of k, k', k''; then, by substituting the values of f just found in the foregoing differential expression, we get

$$A = k \times \iint \frac{2\, d\varphi . d\theta \cos.\theta \sin.^2\theta}{\sin.^2\theta + m\cos.^2\theta \sin.^2\varphi + n\cos.^2\theta \cos.^2\varphi},$$

$$A' = k' \times \iint \frac{m \times 2d\varphi . d\theta \cos.\theta \sin.^2\theta}{m\sin.^2\theta + \cos.^2\theta \sin.^2\varphi + n\cos.^2\theta \cos.^2\varphi},$$

$$A'' = k'' \times \iint \frac{n \times 2d\varphi . d\theta \cos.\theta \sin.^2\theta}{n\sin.^2\theta + \cos.^2\theta \sin.^2\varphi + m\cos.^2\theta \cos.^2\varphi},$$

the limits of the integrals being from $\theta = 0$ and $\varphi = 0$ to $\theta = \frac{\pi}{2}$ and $\varphi = 2\pi$.

31. *To reduce the expressions of the polar attractions to the most simple integrals.*

Let us consider the general expression

$$\iint \frac{d\varphi . d\theta \cos.\theta \sin.^2\theta}{\alpha \sin.^2\theta + \beta \cos.^2\theta \sin.^2\varphi + \gamma \cos.^2\theta \cos.^2\varphi},$$

which includes all the formulas found in (30). Let $p = \alpha \sin.^2\theta + \beta . \cos.^2\theta$, and $q = \alpha \sin.^2\theta + \gamma \cos.^2\theta$; then the above expression will become

$$\iint \frac{d\varphi . d\theta \cos.\theta \sin.^2\theta}{p \sin.^2\varphi + q \cos.^2\varphi}.$$

Suppose $\sqrt{\left(\frac{q}{p}\right)} \cdot \frac{\sin.\varphi}{\cos.\varphi} = \frac{\sin.u}{\cos.u}$; then the preceding expression will become, by substitution,

$$\iint \frac{du . d\theta \cos.\theta \sin.^2\theta}{\sqrt{p \cdot q}};$$

the limits of u being from 0 to 2π; wherefore, by integrating with regard to u, and restoring the values of p and q, the integral becomes

$$2\pi . \int \frac{d\theta . \cos.\theta \sin.^2\theta}{\sqrt{(\alpha \sin.^2\theta + \beta \cos.^2\theta) . (\alpha \sin.^2\theta + \gamma \cos.^2\theta)}}$$

and, by putting $x = \sin.\theta$, the integral, which is to be taken from $\theta = 0$ to $\theta = \frac{\pi}{2}$, or from $x = 0$ to $x = 1$, will become

$$2\pi . \int \frac{x^2\, dx}{\sqrt{[\beta + (\alpha - \beta)x^2] . [\gamma + (\alpha - \gamma)x^2]}}.$$

If now we take α, β, γ, so as to make the assumed expression coincide with the quantities A, A′, A″, respectively, we shall get

$$A = 4\pi k . \int \frac{x^2\, dx}{\sqrt{[m + (1-m)x^2] . [n + (1-n)x^2]}}$$

Attraction.

$$A' = 4\pi k' . \int \frac{m . x^2\, dx}{\sqrt{[1 + (m-1)x^2] . [n + (m-n)x^2]}}$$

$$A'' = 4\pi k'' . \int \frac{n . x^2\, dx}{\sqrt{[1 + (n-1)x^2] . [m + (n-m)x^2]}}$$

These expressions have the inconvenience of containing different factors in the denominators; but they may be reduced to others having the same factors, by putting $x = \frac{\tau}{\sqrt{m + (1-m)\tau^2}}$ in the second, and $x = \frac{\tau}{\sqrt{n + (1-n)\tau^2}}$ in the third; we thus get

$$A = 4\pi k . \int \frac{x^2\, dx}{\sqrt{[m + (1-m)x^2] \cdot [n + (1-n)x^2]}}$$

$$A' = 4\pi k' . \int \frac{m . \tau^2\, d\tau}{[m + (1-m)\tau^2]^{\frac{3}{2}} . [n + (1-n)\tau^2]^{\frac{1}{2}}}$$

$$A'' = 4\pi k'' . \int \frac{n . \tau^2\, d\tau}{[n + (1-n)\tau^2]^{\frac{3}{2}} . [m + (1-m)\tau^2]^{\frac{1}{2}}}$$

Now let

$\frac{1-m}{m} = \frac{k'^2 - k^2}{k^2} = \lambda^2$, and $\frac{1-n}{n} = \frac{k''^2 - k^2}{k^2} = \lambda'^2$:

Also let the mass of the ellipsoid $= M = \frac{4\pi k k' k'}{3}$ $= \frac{4\pi k^3}{3\sqrt{mn}}$; then $\frac{3M}{k^3} = \frac{4\pi}{\sqrt{mn}}$: wherefore, by substitution, we get

$$A = k \cdot \frac{3M}{k^3} \cdot \int \frac{x^2\, dx}{\sqrt{(1 + \lambda^2 x^2) \cdot (1 + \lambda'^2 x^2)}},$$

$$A' = k' \cdot \frac{3M}{k^3} \cdot \int \frac{x^2\, dx}{[1 + \lambda^2 x^2]^{\frac{3}{2}} \cdot [1 + \lambda'^2 x^2]^{\frac{1}{2}}},$$

$$A'' = k'' \cdot \frac{3M}{k^3} \cdot \int \frac{x^2\, dx}{[1 + \lambda^2 x^2]^{\frac{1}{2}} \cdot [1 + \lambda'^2 x^2]^{\frac{3}{2}}},$$

the integrations extending from $x = 0$ to $x = 1$.

These integrals cannot be expressed in finite terms. When λ and λ', or the eccentricities of the ellipsoid, are small, the values of the integrals may easily be found to a sufficient degree of exactness by series. They may likewise be all expressed by means of this fluent, viz.

$$F = \int \frac{dx}{\sqrt{(1 + \lambda^2 x^2) \cdot (1 + \lambda'^2 x^2)}}$$ (from $x = 0$ to $x = 1$) and its partial fluxions. Thus we have, in general,

$$\int \frac{x^2\, dx}{\sqrt{(1 + \lambda^2 x^2) \cdot (1 + \lambda'^2 x^2)}} =$$

$$\frac{x^3}{\sqrt{(1 + \lambda^2 x^2) \cdot (1 + \lambda'^2 x^2)}} + \frac{1}{\lambda} \cdot \left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda'} \cdot \left(\frac{dF}{d\lambda'}\right).$$

Wherefore, making $x = 1$, we get

$$A = k \cdot \frac{3M}{k^3} \cdot \left\{ \frac{1}{\sqrt{(1+\lambda^2) \cdot (1+\lambda'^2)}} + \frac{1}{\lambda}\left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda'} \cdot \left(\frac{dF}{d\lambda'}\right) \right\}$$

$$A' = k' \cdot \frac{3M}{k^3} \cdot \frac{1}{\lambda} \cdot \left(\frac{dF}{d\lambda}\right).$$

$$A'' = k'' \cdot \frac{3M}{k^3} \cdot \frac{1}{\lambda'} \cdot \left(\frac{dF}{d\lambda'}\right).$$

32. *To find the forces with which a homogeneous ellipsoid attracts a particle placed in the surface, or within the solid, in directions perpendicular to the principal sections.*

Let k, k', k'', denote the semiaxes of an ellipsoid, and a, b, c (respectively parallel to k, k', k'') the perpendicular distances of a particle placed in the surface, or within

Attraction. the solid, from the principal sections: then, from what is proved in (29), the attractions we are seeking will be found by multiplying the polar attractions by $\frac{a}{k}, \frac{b}{k'}, \frac{c}{k''}$. Wherefore the forces that urge the particle in the directions of a, b, and c, are respectively $a \times \frac{3M}{k^3}$.

$$\left\{\frac{1}{\sqrt{(1+\lambda^2)\cdot(1+\lambda'^2)}} + \frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda}\right) + \left(\frac{dF}{d\lambda'}\right)\right\};$$

$$b \times \frac{3M}{k^3}\cdot\frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda}\right);$$

$$\text{and } c \times \frac{3M}{k^3}\cdot\frac{1}{\lambda'}\cdot\left(\frac{dF}{d\lambda'}\right):$$

Which formulas serve both for points in the surface and within the solid, for the reason already explained in (25).

33. *To find the attractions of an ellipsoid upon a particle placed without the surface.*

Let k, k', k'', be the semiaxes of the ellipsoid, and a, b, c (respectively parallel to k, k', k'') the co-ordinates of a particle without the surface. Let h, h', h'', so related to k, k', k'', that $h^2 - k^2 = k^2 - k^2$ and $h''^2 - h^2 = k''^2 - k^2$, denote the semiaxes of another ellipsoid, which contains the attracted point in its surface, and has its principal sections in the same planes as the given ellipsoid: then, because the attracted point is in the surface, we have (Def. 2)

$$\frac{a^2}{h^2} + \frac{b^2}{h'^2} + \frac{c^2}{h''^2} = 1;$$

and, because $h'^2 - h^2 = k'^2 - k^2 = \varepsilon^2$, and $h''^2 - h^2 = k''^2 - k^2 = \varepsilon'^2$, we get

$$\frac{a^2}{h^2} + \frac{b^2}{h^2+\varepsilon^2} + \frac{c^2}{h^2+\varepsilon'^2} = 1.$$

This equation now contains only one unknown quantity; and it is plain that one value of h, and only one, can be found from it. For, when $h = 0$, the function on the left hand side is infinitely great; and while h increases from 0 *ad infinitum*, the same function decreases continually from being infinitely great to be infinitely little. When h is found, then $h' = \sqrt{h^2+\varepsilon^2}$, and $h'' = \sqrt{h^2+\varepsilon'^2}$. Because a, b, c, are the co-ordinates of a point in the surface of the ellipsoid, we may suppose $a = h \sin. m$, $b = h' \cos. m \sin. n$, $c = h'' \cos. m \cos. n$; let $a' = k \sin. m$, $b' = k' \cos. m \sin. n$, $c' = k'' \cos. m \cos. n$; or $a' = \frac{k}{h} \times a$, $b' = \frac{k'}{h'} \times b$, $c' = \frac{k''}{h''} \times c$; then a', b', c', will be the co-ordinates of a point in the surface of the given ellipsoid, and consequently it will be within the other solid. Let M' denote the mass of the ellipsoid of which h, h', h'', are the semiaxes; also let $\lambda^2 = \frac{h^2-k^2}{k^2} = \frac{h'^2-k'^2}{k'^2}$; and $\lambda'^2 = \frac{h''^2-k^2}{k^2} = \frac{h''^2-k'^2}{k'^2}$; then, F denoting the same fluent as before, the attractions of this ellipsoid upon the point within it, determined by the co-ordinates a', b', c', in the directions of those co-ordinates, are (32) respectively equal to

$$a' \times \frac{3M'}{k^3}\left\{\frac{1}{\sqrt{(1+\lambda^2)(1+\lambda'^2)}} + \frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda'}\right)\right\},$$

$$b' \times \frac{3M'}{k^3} \times \frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda}\right), \text{ and}$$

$$c' + \frac{3M'}{k^3} \times \frac{1}{\lambda'}\cdot\left(\frac{dF}{d\lambda'}\right).$$

Now, the attractions of the given ellipsoid upon the Attraction. point without the surface, determined by the co-ordinates a, b, c, will be found (26) by multiplying the preceding expressions respectively by $\frac{k'k''}{h'h''}, \frac{k\,k''}{h\,h''}, \frac{k\,k'}{h\,h'}$. Let M be the mass of the given ellipsoid; then $\frac{M}{M'} = \frac{k\,k'\,k''}{h\,h'\,h''}$; consequently $\frac{k'k''}{h'h''} = \frac{M}{M'}\cdot\frac{h}{k} = \frac{M}{M'}\cdot\frac{a}{a'}$; $\frac{k\,k''}{h\,h''} = \frac{M}{M'} \times \frac{b}{b'}$; and $\frac{k\,k'}{h\,h'} = \frac{M}{M'} \times \frac{c}{c'}$; wherefore the attractions of the given ellipsoid upon the point without the surface, determined by a, b, c, in the directions of those co-ordinates, are respectively equal to $a \times \frac{3M}{k^3} \times$

$$\left\{\frac{1}{\sqrt{(1+\lambda^2)(1+\lambda'^2)}} + \frac{1}{\lambda}\left(\frac{dF}{d\lambda}\right) + \frac{1}{\lambda'}\cdot\left(\frac{dF}{d\lambda'}\right)\right\},$$

$$b \times \frac{3M}{k^3} \times \frac{1}{\lambda}\cdot\left(\frac{dF}{d\lambda}\right), \text{ and}$$

$$c \times \frac{3M}{k^3} \times \frac{1}{\lambda'}\cdot\left(\frac{dF}{d\lambda'}\right).$$

The preceding propositions contain a complete theory of homogeneous elliptical spheroids. They enable us to compute the attractive force with which a solid of this kind urges a particle placed anywhere in the surface, within the solid, or without it. It remains, indeed, to find the exact value of the function F in its general form, to which we can do no more than approximate by series; but this is an analytical difficulty which it is impossible to overcome, because the nature of this function is such that it cannot be expressed in finite terms by the received notation of analysis.

In the preceding investigations we have followed the method of Maclaurin for points situated in the surface of a spheroid or within the solid. This method has always been justly admired; but neither its inventor, nor, as far as we know, any other geometer, has applied it, excepting to spheroids of revolution; and it is here, for the first time, extended to ellipsoids. In regard to points without the surface, we have employed the method first given by Mr Ivory, in the *Philosophical Transactions* for 1809. The combination of these two methods has enabled us to derive the attractions of an ellipsoid on a point placed anywhere from the attractions at the poles. Thus, this extremely complicated problem has, by geometrical reasoning of no great difficulty, been reduced to the investigation of the polar attractions, which are the only cases that require a direct computation.

34. *Of the attractions of spheroids composed of elliptical shells that vary in their densities and figures according to any law.*

When a spheroid is composed of concentric elliptical shells of variable density and figure, we may consider every shell as the difference of two homogeneous spheroids of the same density with the shells, and having their surfaces coinciding with the surfaces of the shell. The attractions of the spheroids being computed by the preceding methods, their difference will be equal to the attractions of the shell, and the integral obtained by summing the attractions of all the shells will give the attractions of the heterogeneous spheroid. This case, therefore, gives rise to no new difficulties, except such as are purely mathematical, and depend upon the law according to which the densities and figures of the shells are supposed to vary. (J. I.)

Attribute || Atwood.

ATTRACTION OF MOUNTAINS. See MOUNTAINS.

ATTRIBUTE, in a general sense, is that which may be predicated of a person or thing as a determining characteristic, inherent quality or accident, the negation of which involves either a falsehood, a contradiction, or an absurdity. Thus understanding is an attribute of mind, and extension an attribute of matter. That attribute which the mind conceives as the foundation of all the rest is called its *essential attribute*; thus extension is by some, and solidity by others, considered the essential attribute of matter.

ATTRIBUTES, in *Theology*, the several qualities or perfections of the divine nature.

ATTRIBUTES, in *Logic*, are the predicates of any subject, or what may be affirmed or denied of any thing.

ATTRIBUTIVES, in *Grammar*, are words which are significative of attributes; and thus include adjectives, verbs, and particles, which are attributes of substances, together with adverbs, which denote the attributes only of attributes. Mr Harris, who introduced this distribution of words, denominates the former *attributives of the first order*, and the latter *attributives of the second order*.

ATTRUCK, a river of Persia, which has its rise in a branch of the Elburz Mountains that borders on the northern deserts of Khorassan. It collects the streams of an extensive valley, and of several subordinate glens, and conveys in a westerly direction to the desert a large body of water, which being joined by several other streams, falls into the Caspian Sea at Kooroo-Soofee, 40 or 50 miles to the north of Asterabad.

ATTU, or ATTOO, one of the Aleutian Islands, about 60 miles in length, mountainous, and covered with snow, but inhabited. It is 215 miles east of Behring's Island. Long. 172. E. Lat. 54. N.

ATWOOD, GEORGE, an author celebrated for the accuracy of his mathematical and mechanical investigations, and considered particularly happy in the clearness of his explanations, and the elegance of his experimental illustrations, was born in the early part of the year 1746. He was educated at Westminster school, where he was admitted in 1759. Six years afterwards he was elected *off* to Trinity College, Cambridge. He took his degree of bachelor of arts in 1769, with the rank of third *wrangler*; Dr Parkinson of Christ's College being senior of the year. This distinction was amply sufficient to give him a claim to further advancement in his own college, on the list of which he stood the foremost of his contemporaries; and in due time he obtained a fellowship, and was afterwards one of the tutors of the college. He became master of arts in 1772, and in 1776 was elected a fellow of the Royal Society of London.

The higher branches of the mathematics had, at this period, been making some important advances at Cambridge, under the auspices of Dr Waring, and many of the younger members of the university became diligent labourers in this extensive field. Mr Atwood chose for his peculiar department the illustration of mechanical and experimental philosophy, by elementary investigations and ocular demonstrations of their fundamental truths. He delivered, for several successive years, a course of lectures in the observatory of Trinity College, which were very generally attended and greatly admired. In the year 1784 some circumstances occurred which made it desirable for him to discontinue his residence at Cambridge; and soon afterwards Mr Pitt, who had become acquainted with his merits by attending his lectures, bestowed on him a patent office, which required but little of his attendance, in order to have a claim on the employment of his mathematical abilities in a variety of financial calculations, to which he continued to devote a considerable portion of his time and attention throughout the remainder of his life.

Atwood.

The following, we believe, is a correct list of Mr Atwood's publications:—1. A Description of Experiments to illustrate a Course of Lectures; about 1775 or 1776, 8vo. 2. This work was reprinted, with additions, under the title of An Analysis of a Course of Lectures on the Principles of Natural Philosophy. Cambridge, 1784, 8vo. 3. A General Theory for the Mensuration of the Angle subtended by two objects, of which one is observed by rays after two reflections from plane surfaces, and the other by rays coming directly to the spectator's eye, Phil. Trans. 1781, p. 395. 4. A Treatise on the Rectilinear Motion and Rotation of Bodies, with a Description of Original Experiments relative to the subject. Cambridge, 1784, 8vo. 5. Investigations founded on the Theory of Motion for determining the Times of Vibration of Watch Balances. Phil. Trans. 1794, p. 119. 6. The Construction and Analysis of Geometrical Propositions, determining the positions assumed by homogeneal bodies, which float freely, and at rest, on a fluid's surface; also determining the Stability of Ships, and of other Floating Bodies. Phil. Trans. 1796, p. 46. 7. A Disquisition on the Stability of Ships. Phil. Trans. 1798, p. 201. 8. A Review of the Statutes and Ordinances of Assize which have been established in England from the 4th year of King John, 1202, to the 37th of his present Majesty. Lond. 1801, 4to. 9. A Dissertation on the Construction and Properties of Arches. Lond. 1801, 4to. 10. A Supplement to a Tract entitled a Treatise on the Construction and Properties of Arches, published in the year 1801; and containing Propositions for determining the Weights of the several Sections which constitute an Arch, inferred from the Angles. Also containing a Demonstration of the Angles of the several Sections, when they are inferred from the Weights thereof. To which is added, a Description of Original Experiments to verify and illustrate the Principles in this Treatise. With occasional Remarks on the Construction of an Iron Bridge of one Arch, proposed to be erected over the river Thames at London. Part II. By the author of the first part. Lond. 1804, 4to. Dated 24th November 1803. 11. A Treatise on Optics is mentioned by Nichols as having been partly printed by Bowyer in 1776, but never completed.

It may be very truly asserted that several of these works of Mr Atwood have materially contributed to the progress of science, by multiplying the modes of illustration which experimental exhibitions afford for the assistance of the instructor; at the same time they can scarcely be said to have extended very considerably the bounds of human knowledge, or to have demonstrated that their author was possessed of any extraordinary talent or energy of mind in overcoming great difficulties or in inventing new methods of reasoning. The *Analysis of a Course of Lectures* has been little read; and it bears evident marks of having been composed before Mr Atwood had acquired a habit of accurate reasoning on physical subjects. In the first page, for example, the forces of cohesion and gravitation are completely confounded; and in the third we find the idea of perfect spheres touching each other in a greater or less number of points, notwithstanding the appearance of precision which the author attempts to maintain in his language.

The object of the paper on *Reflection* is, to illustrate and improve the construction of Hadley's quadrant; and Mr Atwood proposes, for some particular purposes in practical astronomy, two new arrangements of the speculums, by which the rays are caused to move in differen planes, and which he considers as affording greater accuracy for the measurement of small angles than the common form of the instrument, although not of general utility, nor very easily adjusted for observation.

The treatise on *Rectilinear Motion and Rotation* exhi-

Atwood. bits a good compendium of the elementary doctrines of mathematical mechanics; but it shows a great deficiency in the knowledge of the higher refinements which had been introduced into that science by Daniel Bernoulli, and Euler, and Lagrange. The properties of simply accelerated and retarded motion are first discussed, and the phenomena of penetration experimentally examined; the laws of varying forces are then investigated, and the properties of the pendulum demonstrated; the vibrations of an elastic chord are calculated, "considering the whole mass to be concentrated in the middle point," as an approximation; and then, instead of imitating and simplifying the elegant but complicated demonstrations of the continental mathematicians, the author most erroneously repeats, in the words of Dr Smith, the exploded doctrine, that "the string, during any instant of its vibration, will coincide with the harmonic curve." The subject of a resistance, varying as the square of the velocity, is next examined; and some useful experiments on the descent of bodies in water are stated in confirmation of the theory. On this occasion, the author observes, with regard to the formation of the different strata of the earth, that bodies disposed to break into large masses, though specifically lighter, may easily have descended more rapidly through a fluid, than denser but more brittle bodies, so that the natural order of densities may thus have become inverted. He next examines the theory of rotation, and relates some very interesting experiments on rectilinear and rotatory motions; and he shows that Emerson and Desaguliers were totally mistaken in asserting that "the momentum produced is always equal to the momentum which produces it." The last section of the work, which is devoted to the subject of free rotation, is the most elaborate of the whole; but it exhibits no material extension of the earlier investigations of the Bernoullis and Professor Vince; nor does it contain the important proposition of Segner, relating to the existence of three axes of permanent rotation, at right angles to each other, in every body, however irregular.

Notwithstanding these partial objections, the work may still, in many respects, be considered as classical. The paper on *Watch-balances* is principally intended to show the advantages which may be obtained, in Mr Mudge's construction, from the effect of subsidiary springs in rendering the vibrations isochronous, their actions being limited to certain portions of the arc of motion. If the author has here again omitted to follow the continental mathematicians in some of their refinements of calculation, it must be confessed that his view of the subject has, in this instance, not only the advantages of simplicity, but also that of a nearer approach to the true practical state of the question, than is to be found in the more complicated determinations which had been the result of the labours of some of his predecessors.

But, whatever may be the merits of these investigations, they appear to be far exceeded in importance by the papers on *Ships*, the first of which obtained for its author the honour of a Copleian medal. Its principal object is to show how much the stability of a ship will commonly vary, when her situation with respect to the horizon is materially altered; and how far the assumptions of theoretical writers, respecting many others of the forces concerned in naval architecture, will generally differ from the true state of these forces when they actually occur in seamanship. In the second part of the investigation, some errors of Bouguer and of Clairbois are pointed out; and the theoretical principles of stability are exemplified by a detailed calculation, adapted to the form and dimensions of a particular vessel, built for the service of the East India Company.

The latter years of our author's life do not appear to have been productive of any material advantage to science. His application to his accustomed pursuits was unremitting, but his health was gradually declining. He had no amusement except such as was afforded by the continued exercise of his mind, with a change of the object only; the laborious game of chess occupying, under the name of a recreation, the hours which he could spare from more productive exertions. He became paralytic some time before his death; and although he partially recovered his health, he did not live to complete his 62d year. Atwood's Machine ‖ Atys.

His researches concerning the history of the *Assize of Bread* must have required the employment of considerable diligence and some judgment in the discovery and selection of materials, although certainly the subject was not chosen for the purpose of affording a display of talent. His opinion respecting the operation of the assize, as favourable to the community, may by some be thought to be justified by the want of success which has hitherto attended the experiment on its suspension; but the advocates of that measure would certainly not admit the trial of a year to be sufficient for appreciating its utility.

The title-pages of the works on *Arches* explain the occasion on which they were brought forward, and at the same time exhibit a specimen of the want of order and precision which seems to have begun to prevail in the author's faculties; while the works themselves betray a neglect of the fundamental principles of mechanics, which is inconceivable in a person who had once reasoned with considerable accuracy on mathematical subjects. An anonymous critic, who is supposed to have been the late Professor Robison (*British Critic*, vol. xxi. January 1804) very decidedly, and at the same time very respectfully, asserted Mr Atwood's error in maintaining that there was no manner of necessity for the condition, that the general curve of equilibrium of an arch should pass through some part of every one of the joints by which it is divided; and in fact we may very easily be convinced of the truth of this principle, if we reflect that the curve of equilibrium is the true representative of the direction of all the forces acting upon each of the blocks, and that, if the whole pressure be anywhere directed to a point situated beyond the limit of the joint, there can be nothing whatever to prevent the rotation of the block on the end of the joint as a centre, until some new position of the block shall have altered the direction of the forces, or until the whole fabric be destroyed. The critic has also very truly remarked that the effects of friction have never been sufficiently considered in such arrangements; but a later author, in an anonymous publication, has removed a considerable part of this difficulty by showing that no other condition is required for determining these effects than that every joint should be perpendicular to the direction of the curve of equilibrium, either accurately or within the limit of a certain angle, which is constant for every substance of the same kind, and which he has termed the angle of repose. (T. T.)

ATWOOD'S MACHINE, an ingenious contrivance for illustrating the doctrine of accelerated motion. See MECHANICS.

ATYS, or ATTYS, in *Greek Mythology*, a beautiful shepherd of Phrygia, beloved by Cybele, who emasculated himself during a fit of madness into which he had been thrown by that goddess in revenge for his infidelity to her. The story is related by Ovid, *Fast.* iv. 221, and differently by other writers. In Pausanias (vii. 17, § 5) may be found the story of Atys killed by a wild boar.

ATYS, a Latin chief, son of Alba, and father of Capys,

Aubagne ‖ Aubigné.

from whom Augustus was said to be descended on the mother's side. This name was also borne by a son of Crœsus, slain by Adrastus.

AUBAGNE, a town of France, department of Bouches-du-Rhone, on the Veaune, ten miles E. of Marseilles. Manufactures of earthenware. Pop. in 1846, 3887.

AUBAINE (probably a corruption of *alibi natus*), an ancient right vested in the king of France, by virtue of which he claimed the inheritance of all foreigners that died within his dominions, notwithstanding any testamentary settlement made by the deceased. An ambassador was not subject to the right of aubaine; and the Swiss, Savoyards, Scots, and Portuguese, were also exempted. This ancient privilege was abolished in 1819.

AUBE, a department of France, watered by the rivers Seine and Aube, from the latter of which it receives its name. It is bounded on the N. by the department of Marne; N.W. by Seine-et-Marne; W. by Yonne; S. by Cote-d'Or; and E. by Haute-Marne. Area about 1,603,500 English acres, of which nearly two-thirds are arable, about one-eighth forest, and somewhat less than one-sixteenth meadow-land. Its general inclination from S.E. to N.W. presents little variety of surface; the N. and N.W. parts are dry and sterile; but the S. and E. districts are very fertile, particularly the valleys, which are admirably adapted for the cultivation of the vine. The principal productions are wheat, rye, oats, potatoes, and wine, of which last about one-half is exported. Chalk and clay are abundant; and there are also quarries of marble, lithographic stone, and building-stone. It is divided into five arrondissements, 26 cantons, and 447 communes. Pop. in 1851, 265,247. The arrondissements, with their populations, are as follows:—Troyes, 95,878; Arcis-sur-Aube, 36,364; Nogent-sur-Seine, 35,211; Bar-sur-Aube, 44,347; Bar-sur-Seine, 53,447. Its manufactures are cotton, linen, and woollen goods, glass, earthenware, paper, sugar, ropes, &c. The capital is Troyes.

AUBENAS, a town of France, department of Ardeche, near the river of that name, 14 miles S.W. of Privas. It is beautifully situated on the slope of a hill, but its streets generally are crooked, narrow, and filthy. It is surrounded by a ruinous wall flanked with towers, and has an old castle. Manufactures, silk and woollen. Pop. 4262.

AUBIGNÉ, Théodore-Agrippa D', the bold, able, but somewhat irascible historian of the French Huguenots, was born at St Maury, in the province of Saintonge, in 1550. From his father, who fell fighting in the cause of religious liberty, he inherited an ardent attachment to the Protestant cause; and while still a youth, escaping from his guardians, he took part in the third religious war of that period. He had the good fortune to survive the massacre of St Bartholomew's day, and fled to the court of the king of Navarre, afterwards Henry IV.; but though his services, both in the council and the field, were esteemed by Henry, D'Aubigné more than once retired in disgust from court, where his temper had created many enemies. Yet the king appears always to have had a high opinion of his integrity; and, contrary to the advice of his friends, intrusted him with the custody of the king's formidable rival, Cardinal Bourbon, when a prisoner. He was faithful to his trust in his castle of Maillezais, to the government of which he was promoted by Henry, and whither he retired on the conversion of the king in 1593. There he wrote several able controversial dissertations, and composed his principal work, *L'Histoire Universelle*, which the Catholic party used every means to suppress, and the parliament of Paris ordered to be burnt by the executioner in 1620. The government made many attempts to induce him to resign his stronghold; and finding it no longer tenable, he in that year resigned it into the hands of the Duc de Rohan, the leader of the Huguenots, and retired to Geneva, where he died in 1630, at the age of 80. (T. S. T.)

Aubigny ‖ Auch.

AUBIGNY, or Avigny, a town of France, in the department of Cher and arrondissement of Sancerre. Pop. 2381. It gives a title to the Duke of Richmond.

AUBREY, John, descended from an ancient family in Wiltshire, was born in 1626. He made the history and antiquities of England his peculiar study, and contributed considerable assistance to the *Monasticon Anglicanum*. He succeeded to several good estates; but law-suits and other misfortunes consumed them all, and reduced him to absolute want. In this extremity he found a valuable benefactress in the Lady Long of Draycot in Wilts, who gave him an apartment in her house, and supported him till his death, which took place at Oxford in 1697. He was a man of considerable ability, learning, and application, but credulous, and tinctured with superstition. He wrote *Miscellanies*, and *A Perambulation of the County of Surry*, in 5 vols. 8vo. In 1813, his *Lives of Eminent Men*, and a *Collection of Letters*, were published from the originals preserved in the Bodleian Library, in 3 vols. 8vo. The Lives are replete with curious matter; and that of Hobbes, in particular, is very full and elaborate.

AUBURN properly signifies the colour produced by scorching, being derived from *brennan, burn*. As applied to hair, it denotes brown with a tinge of red or russet.

Auburn, the capital of the county of Cayuga, in the state of New York. It is remarkable for its great penitentiary or state prison, in which the experiment of solitary confinement for crimes was made, but abandoned after two years' experience of its injurious effects on the minds and bodies of the prisoners. After this the silent system was adopted. (See Roscoe *on Penal Jurisprudence*.) The building is an oblong of 1000 by 500 feet, and is surrounded by a wall 3000 feet in length, and 30 feet high. A Presbyterian theological seminary was founded here in 1821, and is now in a very flourishing condition. There are also several churches and schools, two academies, a museum, two banks, and manufactures of woollen and cotton stuffs, leather, &c. Pop. in 1850, 9548.

AUBUSSON, an arrondissement in the department of Creuse, in France. Area, 802 square miles. It is divided into 10 cantons, and 104 communes. Pop. in 1851, 106,619. The capital, of the same name, is on the banks of the river Creuse. Pop. 5586. Its manufactures are silk, carpets, and cloths.

AUCH, one of the most ancient cities of France, capital of the department of Gers, and of the arrondissement of the same name. In Cæsar's time this was the capital of the Ausci. It was afterwards the capital of Gascony; and when that district was divided into counties, it became the capital of Armagnac. The site of the modern town does not exactly coincide with that of the ancient, being on the opposite (the left) bank of the river Gers. It was probably destroyed by the Saracens about A.D. 724, and was afterwards rebuilt in its present picturesque situation on the slope of a hill. On the opposite side of the river, and occupying the site of the ancient city, is a considerable suburb, which is connected with the town by a bridge. The streets are generally regular and well built, and a fine promenade in the upper part of the town affords a magnificent view of the surrounding country. Auch is the seat of an archbishopric; tribunals of commerce and primary jurisdiction; and has a royal college; an agricultural society; a theological seminary, with a museum and a library of 15,000 volumes; a small public library; a theatre, &c. The cathedral of St Mary, one of the most magnificent in France, was commenced in the reign of Charles VIII. (1489), and finished in that of Louis XV. It exhibits several styles of architecture, and contains many elegant monuments. The hotel of the prefecture, formerly the archiepiscopal palace, is a vast and noble edifice. The principal manufactures are hats, various kinds of linen and cotton stuffs, leather, &c., and there is a considerable trade, especially in the brandies of Armagnac.

Auchterarder || Auction.

Pop. in 1851, 9935. The arrondissement of the same name contains 6 cantons, 84 communes, and 61,925 inhabitants.

AUCHTERARDER, a town and parish of Scotland, county of Perth, 15 miles W.S.W. of Perth. The town consists of a single street about a mile in length. It was formerly a royal burgh, but is now disfranchised. Near it is an ancient castle, said to have been a hunting-seat of Malcolm Canmore. Pop. of town in 1851, 2520.

AUCHTERMUCHTY, a royal burgh and parish of Scotland, county of Fife, 8 miles W.S.W. of Cupar. The town is irregularly built on an elevated site, and is divided by the Leverspool, a rapid streamlet which runs down its centre. The principal manufacture is linen. It formerly sent a member to parliament, but now votes in returning the member for the county. It is governed by three bailies and fifteen councillors. Pop. of burgh in 1851, 2673.

AUCKLAND, the capital of New Zealand, which see.

AUCKLAND–BISHOPS, a market-town in the ward of Darlington and county of Durham, ten miles from the city of Durham. It is beautifully situated on an eminence near the confluence of the rivers Wear and Gaunless. The descent on each side is partly formed into hanging gardens, the houses occupying the brow and remainder of the declivity. The palace of the Bishop of Durham stands at the north angle of the town. The parish church, a Gothic structure, is one mile distant, at Auckland St Andrews. Manufactures, muslins and other cotton goods. Pop. in 1851, 4400.

AUCKLAND *Islands*. See AUSTRALASIA.

AUCTION, a well-known mode of selling property, in open competition, to the highest offerer, by means of an agent or auctioneer. When the property is of considerable value, a person is sometimes appointed to superintend the sale, who is denominated judge of the roup, and acts as an arbiter in settling any disputes that may arise. The terms of the sale may be regulated at the will of the exposer, provided they are distinctly announced to the public beforehand. The party offering the highest price is declared the purchaser. When formal articles of sale are employed, they commonly regulate how much each offer shall exceed the previous one; whether the exposer shall be allowed to make an offer, or to withdraw the subject, if the highest offer does not amount to a given sum; and sometimes it is declared that an instalment of the price shall be payable instantly, or that security shall be found within a stipulated period; failing which the immediately preceding offerer is preferred. Secret contrivances, either to raise or depreciate the price, are unlawful. The seller must not attempt to practise any imposition on the public; neither are the bidders permitted to adopt any unfair means to prevent the natural operation of free competition. Where any such thing is detected, not only is the sale vitiated, but reparation is due to the injured party. For example, the secret employment by the seller of a friend to raise the price by making a fictitious offer is fraudulent, and entitles the highest offerer, on detecting it, to repudiate the transaction, or (in case he has been outbidden by such fictitious party) to demand the property at the price which he fairly offered. On the other hand, the obligation on the part of the public to act fairly is equally stringent. Accordingly, if two or more individuals combine to withhold their biddings that one of their number may purchase cheaply in order to divide among them the expected profit, or if a bidder were to give money to others to induce them to refrain from bidding, the exposer is entitled to have the sale declared void; on the ground that such a secret combination or paction obviously deprived him of the advantage which he expected from that competition which a public sale is intended to secure.

Formerly a duty was payable to government on the price realized; but at present it is only required that an annual license, which costs L.10, be taken out by the auctioneer.

Aude || Auditor.

AUDE, a southern department of France, forming part of the old province of Languedoc, bounded on the E. by the Mediterranean, N. by the departments of Herault and Tarn, N.W. by Upper Garonne, W. by Ariege, and S. by that of Eastern Pyrenees. It lies between Lat. 42. 40. and 43. 30. N.; is 80 miles in length from E. to W., and 60 miles in breadth from N. to S. Area, 2341 square miles.

The department of Aude is traversed on its western boundary from south to north by a mountain range of medium height, which unites the Pyrenees with the Southern Cevennes; and its northern frontier is occupied by the Black Mountains, the most western part of the Cevennes chain. The Corbieres, a branch of the Pyrenees, runs in a S.W. and N.E. direction along the southern district. The Aude, its principal river, has its entire course in this department, except a small part towards its source in the Eastern Pyrenees. Flowing first northwards, at Carcassonne it turns abruptly to the E., and continues in that direction till it reaches the sea on the confines of the department of Herault. Its principal affluents on the left are the Rebenti, Cougain, Lou, Rougeane, Orbiel, Argent-Double, and Ceysse; on the right, the Guette, Salse, and Orbieu. The canal of Languedoc, which unites the Atlantic with the Mediterranean, traverses the department from E. to W. The lowness of the coast causes a series of large lagunes; the chief of which are those of Bages, Lijean, Narbonne, Palme, and Leucate. Various kinds of wild animals, as the chamois, bear, wild boar, wolf, fox, and badger, inhabit the mountains and forests; game of all kinds is plentiful; and the coast and lagunes abound in fish. It has mines of iron, copper, lead, manganese, cobalt, and antimony. Besides the beautiful marbles of Cascastel and Caunes, there are quarries of lithographic stones, gypsum, limestone, and slate. At Tuchan and Durban are two coal mines of excellent quality, but the veins are not thick. The mountains contain many mineral springs, both cold and thermal.

The agriculture of this department is in a very flourishing condition, more than four-ninths of the soil being under grain, and about one-twelfth in vineyards. About a ninth part is occupied by woods and forests; more than two-sevenths are waste land; and the meadows are extensive and well watered. The grain produce considerably exceeds the consumption, but the vine constitutes the principal agricultural wealth. Olives are also extensively cultivated, and the honey of Aude is much esteemed. Besides important manufactures of cloths, combs, jet ornaments, and casks, there are paper-mills, distilleries, tanneries, and extensive iron and salt works.

This department contains 4 arrondissements, 31 cantons, 433 communes. The population in 1851 was as follows:—

	Cantons.	Pop.
Carcassonne	12	94,970
Limoux	8	75,229
Narbonne	6	64,400
Castelnaudary	5	55,148
	31	289,747

AUDEBERT, JEAN-BAPTISTE, an eminent naturalist and delineator of animals, born at Rochefort in 1759, died in 1800. He introduced a new era in the art of depicting animals, and acquired great celebrity by the illustrations he furnished for several well-known works on subjects of natural history. His first folio, *Histoire Naturelle des Singes et des Makis, &c.*, is a beautiful and valuable work; but his *Histoire des Colibris, des Oiseaux-mouches, des Jacamars et des Promerops*, published in folio at Paris in 1802, is superb, and is also remarkable for the masterly style of the diagnosis and descriptions.

AUDITOR, in a general sense, a hearer, or one who listens or attends to anything.

AUDITOR, *in English Law*, is an officer of the

Auditors ‖ Audæus.

some other great person, who, by examining yearly the accounts of the under officers, makes up a general book, which shows the difference between their receipts and charges, and their several allowances.

Auditors of the Imprest were the officers of the exchequer, who had formerly the charge of auditing the great accounts of the customs, naval and military expenses, &c. Their patents were vacated by the 25th Geo. III. cap. 52, and a compensation granted of L.7000 per annum (§ 3). The duties of the office were transferred to the *commissioners for auditing the public accounts*, appointed by § 4.

The commissioners were at first *five* in number, of whom *two* were required to be the comptrollers of the army accounts, and continued to be commissioners so long only as they held that office. Their tenure of office is expressed to be *quamdiu se bene gesserint*. Power was then given by the 45th Geo. III. cap. 91, for the appointment of *three* commissioners as an additional board for examining and auditing the public extraordinary accounts under the direction of the treasury, such commissioners not to be members of parliament (§ 7). But afterwards, by the 46th Geo. III. cap. 141, the number was increased to *ten*, who should hold their office "during good behaviour," with a salary to the chairman of L.1500, and to the other commissioners of L.1200 per annum. And it was also provided that the comptrollers of army accounts should cease to be auditors of public accounts, and that no commissioner should be a member of parliament; and in case of a vacancy, the appointment thereto could not be made without the authority of parliament, unless the number should be reduced to five or less. Five of the commissioners constitute a general board.

The powers and duties of the commissioners have been from time to time augmented. The various statutes by which these changes have been effected, and the several offices brought under their audit, are as follow:—

The three offices of *auditors of the Land Revenue* on the respective deaths of the then holders: 39th Geo. III., cap. 83, § 1.

The accounts of the receipts and expenditure of *Colonial Revenues* in the islands of Ceylon, Mauritius, Malta, Trinidad, and the settlements of the Cape of Good Hope: 2d Will. IV. cap. 26. It appears that under the 54th Geo. III. cap. 184, three commissioners were appointed for this purpose, at salaries of L.1000, and two at L.800 each, whose powers were continued by the 59th Geo. III. cap. 67, and the 1st Geo. IV. cap. 65, and rendered perpetual by the 1st and 2d Geo. IV. cap. 121.

The powers and duties of the *commissioners of public accounts in Ireland:* 2d and 3d Will. IV. cap. 99.

The duties of auditing and passing *sheriff's* accounts: 3d and 4th Will. IV. cap. 99, § 8.

The audit of the accounts of all moneys which by any act of parliament are under the control of the *commissioners of Her Majesty's woods and forests:* 7th and 8th Vict. cap. 89; of the accounts of the *treasurers of the county courts:* 9th and 10th Vict. cap. 95, § 45; and of the *excise revenue*, on the abolition of the office of auditor of the excise, which was created by the 4th Vict. cap. 20, § 14; 12th Vict. cap. 1.

Under the Municipal Corporations Act, 5th and 6th Will. IV. cap. 76, the burgesses annually elect from among those qualified to be councillors, two auditors to audit *the accounts of the borough*, who are by the 7th Will. IV. and 1st Vict. cap. 78, § 15, disqualified to be of the council.

In Scotland there is an auditor attached to the Court of Session, who officially examines accounts when costs are given, whose certificate or taxation is essential to the enforcement of payment. (R. M—M.)

AUDITORIUM, in the ancient churches, was the nave, or that part of the church where the auditors stood to hear and be instructed.

AUDÆUS, or AUDIUS, a reformer of the fourth century, by birth a Mesopotamian. He suffered much persecution from the Syrian clergy for his fearless censure of their irregular lives; and was eventually banished into Scythia, where, after propagating his sect with good success, he died at an advanced age, about A.D. 370. The Audæans celebrated the feast of Easter on the same day with the Jewish passover, and they were also charged with Anthropomorphism, or attributing to the Deity a human shape. They founded this opinion on Genesis i. 26. Mosheim's *Instit. of Eccles. Hist.*

Audouin ‖ Audran.

AUDOUIN, JEAN VICTOR, a distinguished French entomologist, was born at Paris, April 27. 1797. He began the study of law, but was diverted from it by his strong predilection for natural history, which subsequently led him to enter the medical profession. In 1824, he was appointed assistant to Latreille in the entomological chair at the museum of natural history, and succeeded him in 1833. He established in 1828, in conjunction with Dumas and Adolphe Brongniart, the *Annales des Sciences Naturelles*, to which he made numerous valuable contributions, generally in co-operation with M. Milne Edwards. Besides these, the greater part of his papers are contained in the Transactions of the Entomological Society, of which he was one of the founders, and for many years president. He died in 1841, more from the effects of mental than of bodily exhaustion.

AUDRAN, CLAUDE, a French engraver, was the son of Louis Audran, an officer belonging to the wolf-hunters in the reign of Henry IV. of France. He was born at Paris in 1592, and died at Lyons in 1677. Though he never acquired much reputation by his own works, he was the father of three great artists, Germain, Claude, and Girard; the last of whom has immortalized the name of the family.

AUDRAN, *Carl*, brother to the preceding, was born at Paris in 1594. In his infancy he discovered a great taste for the arts; and to perfect himself in engraving, went to Rome, where he produced several prints which did him great honour. On his return he adopted that species of engraving which is performed with the graver only. He settled at Paris, where he died in 1674. In the early part of his life he marked his prints with C, or the name of Carl, till his brother Claude published some plates with the initial only of his baptismal name, when, for distinction's sake, he used the letter K.

AUDRAN, *Germain*, the eldest son of Claude, was born in 1631, at Lyons. Not content with the instructions of his father, he went to Paris and perfected himself under his uncle Carl; and on his return to Lyons, published several prints which contributed much to his reputation. He was made a member of the academy established in that town, and chosen a professor. He died at Lyons in 1710, and left behind him four sons, all artists, namely, Claude, Benoit, Jean, and Louis.

AUDRAN, *Claude*, the second of this name, and second son to Claude above mentioned, was born at Lyons in 1639, and went to Rome to study painting. On his return he was employed by Le Brun to assist him in various works. He was made an academician in 1675, and died at Paris in 1684.

AUDRAN, *Girard*, or *Gérard*, the most celebrated artist of the whole family, was the third son of the Claude Audran first mentioned, and was born at Lyons in 1640. He was taught the first principles of design and engraving by his father; and, following the example of his brother, went to Paris, and afterwards to Rome, to perfect himself in his art. At Rome, where he resided three years, he engraved several fine plates. That great patron of the arts, M. Colbert, was so struck with the beauty of Audran's works, that he persuaded Louis XIV. to recal him to Paris. On his return he applied himself assiduously to engraving, and was appointed engraver to the king, from whom he received great encouragement. In the year 1681 he was admitted to the council of the Royal Academy. He died at Paris in 1703. His greatest works are his engravings of Le Brun's *Battles of Alexander*.

"He was," says the Abbé Fontenai, "the most celebrated

Audran || Audubon.

engraver that ever existed in the historical line. We have several subjects which he engraved from his own designs, that manifested as much taste as character and facility. But in the *Battles of Alexander* he surpassed even the expectations of Le Brun himself."

AUDRAN, *Benoit*, the second son of Germain Audran, was born at Lyons in 1661. He studied, first under his father, and afterwards at Paris, under his uncle Girard. Though he never equalled his preceptor, yet he deservedly acquired a high reputation by the boldness and clearness of his style. He died at Louzouer in 1721.

AUDRAN, *Jean*, the third son of Germain Audran, was born at Lyons in 1667. After having received instructions from his father, he went to Paris to perfect himself in the art of engraving under his uncle Girard, next to whom he was the most distinguished member of his family. At the age of twenty his genius began to display itself in a surprising manner; and his subsequent success was such, that in 1707 he obtained the title of engraver to the king, and had a pension allowed him by His Majesty, with apartments in the Gobelins; and the following year he was made a member of the Royal Academy. He was eighty years of age before he quitted the graver, and nearly ninety when he died. The best prints of this artist are those which appear not so pleasing to the eye at first sight. In these the etching constitutes a great part; and he has finished them in a bold rough style. The *Rape of the Sabines*, after Poussin, is considered his masterpiece.

AUDRAN, *Louis*, the last son of Germain Audran, was born at Lyons in 1670, and thence went to Paris, after the example of his brothers, to complete his studies in the school of his uncle Girard. He died suddenly at Paris in 1712, before he had produced any great number of prints. His best work is *The Seven Acts of Mercy*.

AUDRAN, *Benoit, the younger*, was the son of Jean Audran, and nephew to the former Benoit. He engraved but few plates, and, in point of merit, is vastly inferior to his uncle.

AUDUBON, JEAN JACQUES, the well-known naturalist, was born in Louisiana in 1781, where his parents, who were French Protestants, took up their residence while it was still a Spanish colony. They afterwards settled in Pennsylvania. He informed the writer of this memoir, that from his early years he had a passion for observing the habits and appearances of birds, and attempting delineations of them from nature. At the age of fifteen he was sent to Paris, and remained there about two years, when among other studies he took some lessons in the drawing-school of David. On returning to America his father established him in a plantation in Pennsylvania, and he soon after married. But neither the management of his plantation, nor his domestic relations as a husband and a father, could damp his ardour for natural history. This favourite pursuit often led him to explore the depths of the primeval forests of America in long and sometimes hazardous expeditions, far from his family and his home. For the fifteen years that followed 1810, he annually continued these excursions, and in that school acquired the facility of making those spirited drawings of birds that give such value to his magnificent work, *The Birds of America*. At that period he had not dreamt of any publication of his labours; and has informed us "it was not the desire of fame that prompted to those long exiles; it was simply the enjoyment of nature."

He afterwards removed with his family to the village of Henderson on the banks of the Ohio, where he remained for several years, pursuing his ornithological propensities; and at length set out for Philadelphia with a portfolio containing 200 sheets filled with coloured delineations of about 1000 birds. Business obliged him to quit Philadelphia unexpectedly for some weeks, and he deposited his portfolio in the warehouse of a friend; but judge of his horror and mortification at finding on his return, that these precious fruits of his wanderings and his labours had been totally destroyed by rats! Audubon.

The shock threw him into a fever of several weeks' duration, that had well-nigh proved mortal. But his native energy returned with returning health; and he resumed his gun and his gamebag, his pencils, and his drawing-book, and replunged into the recesses of the backwoods. In eighteen months passed far from home, he had again filled his portfolio; and then rejoined his family, who had in the mean time gone to Louisiana.

After a short sojourn there, he bade them again adieu; and set out for the Old World, to exhibit to the ornithologists of Europe the riches of the New World in that department of natural history.

Audubon arrived in 1826 at Liverpool, where the merits of his spirited delineations of American birds were immediately recognized, and greatly admired by his present biographer and several other friends, who advised an exhibition of them to the public, in the galleries of the Royal Institution of that town. The exhibition was repeated at Manchester, and at Edinburgh, where they were no less admired. When he proposed to publish a work on the birds of America, several naturalists advised him to issue the work in large quarto, as the most useful size for the lovers of natural history, and the most likely to afford him a sufficient number of subscribers to remunerate his labours. At first he yielded to this advice, and acknowledged its soundness; but finally he decided that his work should eclipse every other ornithological publication. Every bird was to be delineated of the *size of life*, and to each species a whole page was to be devoted; consequently the largest *elephant folio* paper was to receive the impressions. In such enormous pages the white headed-eagle and the wild turkey certainly fill the space with good effect; but to occupy such pages with a humming-bird or a fly-catcher, seemed to his more sober friends rather extravagant. It is true that his beautiful drawings of plants and flowers, which he introduced with the smaller birds, were often very spirited and characteristic; but size necessarily increased the expense of the work so much as to put it beyond the reach of most scientific naturalists; which accounts for the small number of persons whom, for a considerable time, he could reckon among his supporters in this gigantic undertaking. The extreme beauty, however, of this splendid work, extorted the applause of the wealthy and the eminent in station; and a sufficient number of subscribers was obtained in Britain and America, during the ten or twelve years that the work was going through the press, to indemnify him for the vast cost of the publication; yet left him a very moderate compensation for his uncommon industry and skill. We are convinced that had a quarto size been adopted, with a scale of the size for each species, it would have been far more advantageous to the gifted and indefatigable author.

The first volume of this noble work was published in the end of the year 1830, the second in 1834, the third in 1837, and the fourth and last in 1839. The whole consists of 435 coloured plates, containing 1055 figures of birds the size of life. It is certainly the most magnificent work of the kind ever given to the world, and is well characterized by Cuvier, "C'est le plus magnifique monument que l'art ait encore élevé à la Nature."

During its preparation and publication, Audubon made several excursions from Great Britain. In the summer of 1828, he visited Paris, where he obtained the acquaintance and gained the high approbation of Cuvier, Humboldt, and many other celebrated naturalists. The following winter he passed in London. In April of 1830 he revisited the United States of America; and again explored the forests of the central and southern federal territories. In the following year he returned to London and Edinburgh; but the August of 1831 found him again in New York. The fol-

Auerstadt ‖ Augeas.

lowing winter and spring he spent in Florida and South Carolina; and in the summer of 1832, he set out for the Northern States, with an intention of studying the annual migrations of birds, particularly of the passenger pigeon, of which he has given a striking description; but his career was arrested at Boston by a severe attack of cholera, which detained him there till the middle of August. After that he explored the coasts, the lakes, rivers, and mountains of N. America, from Labrador and Canada to Florida, during a series of laborious journeys, that occupied him for three years. From Charleston, accompanied by his wife and family, he took his third departure for Britain.

Before, however, he had quitted these islands, he had begun to publish at Edinburgh his *American Ornithological Biography*, which at length filled five very large octavo volumes. The first appeared in 1831, and the last in 1839. This book is admirable for the vivid pictures it presents of the habits of the birds, and the adventures of the naturalist. The descriptions are characteristically accurate and interesting.

M. Audubon spoke English fluently, with a foreign accent; and he wrote it easily, but with an occasional foreign idiom. It is true, as he informed us, that in this publication the style was corrected by his friend the late Professor Macgillivray of Aberdeen; but from having examined Audubon's MS. notes, before he had ever met Mr Macgillivray, we can positively state, that any similarity to be discerned between their acknowledged writings on natural history, may be as justly attributed to an imitation of the spirited descriptions of Audubon by his friendly assistant, as to any obligation of Audubon to that author for the graphic style of his narrative. We may add, that Audubon always acknowledged the services of Mr Macgillivray in terms of enthusiastic friendship and regard.

In 1839 Audubon bade a final adieu to Europe; and returning to his native country, he published in a more popular form his *Birds of America*, in seven octavo volumes, the last of which appeared in 1844.

His ardent love of nature still prompted him to new enterprizes, and he set out on fresh excursions; but in these he was accompanied by his two sons, and one or two other individuals, instead of his former solitary rambles. The result of these excursions was the projection of a new work, *The Quadrupeds of America*, in atlas folio, and also a *Biography of American Quadrupeds;* both of which were commenced at Philadelphia in 1840. The latter was completed in 1850, and is, perhaps, even superior to his *Ornithological Biography*.

To great intelligence in observing, and accuracy in delineating nature, to a vigorous handsome frame, and pleasing expressive features, M. Audubon united very estimable mental qualities, and a deep sense of religion without a trace of bigotry. His conversation was animated and instructive; his manner unassuming; and he always spoke with gratitude to Heaven for the very happy life he had been permitted to enjoy.

He died, after a short illness, in his own residence on the banks of the Hudson, at New York, on the 27th of January 1851. (T. S. T.)

AUERSTADT, a small village in the Prussian province of Saxony, celebrated for the victory more commonly known by the name of the neighbouring city of Jena, which the French gained over the Prussians in October 1806.

AUGEAS (Αὐγέας or Αὐγείας), a fabulous king of Elis, famed for his stable, which contained 3000 oxen, and had not been cleansed for thirty years. Hercules was desired to clear away the filth from this stable in one day; and Augeas promised, if he performed it, to give him a tenth part of the cattle. This task Hercules is said to have executed by turning the course of the rivers Alpheus and Peneus through the stable; and when Augeas refused to keep his engagement, Hercules slew him, and gave his kingdom to his son Phyleus, who had shown an abhorrence of his father's insincerity.

Augereau ‖ Augsburg.

AUGEREAU, Pierre François Charles, Duke of Castiglione, was the son of obscure parents, and born in 1757. After enlisting in the armies of France, he afterwards entered into the Neapolitan service; but retired from it and joined the Republican army that watched the movements of Spain in 1792. He became an officer in the army of Italy, and distinguished himself in storming the Bridge of Lodi in 1796. Next year he took part with Barras and the Directory, and was the prime agent in the revolution of Fructidor; but his jealousy of his former comrade, Buonaparte, prevented their intimacy; and he had the honour of being one of the general officers not privy to the noted revolution of the 18th of Brumaire (Nov. 9.) 1799. Mutual jealousy kept them aloof until 1805, when Augereau was made a marshal of the French Empire, and appointed to the command of the expedition against the Voralberg, which he quickly subdued. He distinguished himself greatly in the battles of Jena and Eylau. In 1809–10 he commanded the French in Catalonia, and tarnished his laurels by unnecessary cruelty to the Spaniards; but he was again more honourably conspicuous in the campaign of 1813, especially in the terrible battle of Leipzig. In 1814 he submitted, and retained a command under the Bourbons; and in the following year he refused to join Napoleon on his escape from Elba. He had the painful task of being one of the commission that sat on the trial of Marshal Ney, whom he did not long survive, as he died of dropsy in 1816. (T. S. T.)

AUGRE, or Auger, an instrument used by carpenters and joiners to bore large round holes. It consists of a wooden handle and an iron shank, terminated at bottom with a steel bit. *Auger* is likewise the name of an instrument of a similar kind which is used for boring into the soil in order to ascertain the nature of the substrata, or the existence of water. It has connecting rods to adapt it to the different depths required.

AUGSBURG, a celebrated city of Germany, capital of the circle of the Upper Danube, in Bavaria. On the conquest of Rhætia by Drusus, Augustus established a Roman colony here, about B.C. 14, and gave it the name of *Augusta Vindelicorum*. In the fifth century it was sacked by the Huns, and afterwards came under the power of the Frankish kings. It was almost entirely destroyed in the war of Charlemagne against Thassilon, Duke of Bavaria; and after the dissolution and division of that empire, it fell into the hands of the Dukes of Suabia. After this it rose rapidly into importance as a manufacturing and commercial town, and about the middle of the thirteenth century it was raised to the rank of a free imperial city, which it retained till 1806, when it was annexed to the kingdom of Bavaria.

This city is pleasantly situated in an extensive and fertile plain, between the rivers Werlach and Lech, 36 miles W.N.W. of Munich, with which it is connected by railway. Lat. 48. 21. 46. Long. 10. 54. 42. E. Its fortifications were dismantled in 1703, and though still surrounded by walls and ditches, these would now form but a poor defence against an enemy. The town is generally ill-built; one street, however (Maximilian Street), is remarkable both for its breadth and architectural magnificence. The public buildings of Augsburg are worthy of notice. Among these is the town-hall, said to be the finest in Germany, built in the beginning of the seventeenth century. One of its rooms, called the "Golden Hall" from the profusion of its gilding, is 110 feet long, 58 broad, and 52 high. The palace of the bishops, where the memorable Confession of Faith was presented to Charles V., is now used for government offices. There are also a cathedral, various churches and chapels, a school of arts, a polytechnic institution, a picture gallery, gymnasium, deaf-mute institution, orphan asylum, public library, &c. The "Fuggerei," built in 1519 by the bro-

Augsburg Confession || Augustin.

thers Fugger, consists of 106 small houses let to indigent citizens at a mere nominal rent. The manufactures of Augsburg are various and important, consisting of woollen, linen, cotton, and silk goods, watches, jewellery, mathematical instruments, machinery, leather, paper, &c. The *Allgemeine Zeitung*, or Augsburg Gazette, is published here. It is the principal seat of the commerce of S. Germany, and of the commercial transactions between that and the S. of Europe. Pop. (1849), including the garrison, 37,986.

AUGSBURG CONFESSION. This celebrated confession of faith was drawn up by Luther and Melanchthon, on behalf of themselves and other reformers, and presented in 1530 to the Emperor Charles V. at the diet of Augusta or Augsburg, in the name of the evangelic body. It contains 28 chapters, of which the greater part is occupied with an impartial representation of the religious opinions of the Protestants, and the remainder in pointing out the errors and abuses that occasioned their separation from the Church of Rome.

AUGUR, an officer among the ancient Romans, originally appointed to foretell future events by the chattering, flight, and feeding of birds; though afterwards they divined also by prodigies, lightning, &c. There was a college or community of these functionaries, consisting originally of three members. Afterwards the number was increased to nine, four of whom were patricians and five plebeians. This number was augmented by Sulla to fifteen, and Julius Cæsar added another. They bore an augural staff or wand, as the ensign of their authority; and their dignity was so much respected that they were never deprived of office, even though convicted of the most enormous crimes.

AUGURY, in its proper sense, the art of foretelling future events by observations on birds; though it is used by some writers in a more general signification, as comprising all the different kinds of divination.

AUGUST, in *Chronology*, the eighth month of our year; so called in honour of Augustus Cæsar, who in this month was created consul, thrice triumphed in Rome, subdued Egypt, and made an end of the civil wars.

AUGUSTA, capital of the county of Kennebec, in the state of Maine, N. America, is situated on both sides of the river Kennebec, 43 miles from the ocean. The river is here crossed by a fine bridge, 520 feet in length; and the town is well laid out, containing a handsome state-house of white granite, an arsenal, lunatic asylum, &c. Population (1850) 8231.

AUGUSTA, a city in the state of Georgia, on the Savannah river, and capital of the county of Richmond; 96 miles from Milledgeville, with which it is connected by railway. It is situated in a district rich in cotton, large quantities of which are conveyed to Charleston and Savannah. The town is regularly laid out, and handsomely built, the streets crossing each other at right angles. Pop. 6403.

AUGUSTA, or AGOSTA, a well-built and fortified city in the intendancy of Catania, in Sicily. It stands on a tongue of land near Cape Croce, and has a good harbour, from which salt, honey, oil, and wine are exported. Pop. 15,000.

AUGUSTALES, in *Roman Antiquity*, an epithet given to the flamens or priests appointed to sacrifice to Augustus after his deification. The *ludi*, or games, celebrated in honour of the same prince on the 4th day before the ides of October, were also called *Augustales*, or *Augustalia*.

AUGUSTALIS PRÆFECTUS, a title peculiar to the Roman magistrate who governed Egypt, with a power much like that of a proconsul in other provinces.

AUGUSTAN AGE, a term used to designate the most brilliant period of Roman literature, or the age of Augustus, when Virgil, Horace, Cicero, Ovid, Catullus, Tibullus, and other great geniuses flourished.

AUGUSTAN CONFESSION. See AUGSBURG CONFESSION.

AUGUSTIN, or AUSTIN, ST, the first archbishop of Canterbury, was originally a monk in the convent of St Andrew at Rome, and educated under St Gregory, afterwards Pope Gregory I., by whom he was sent into Britain with forty other monks of the same order, about the year 596, to convert the English Saxons to Christianity. The missionaries landed in the isle of Thanet; and having sent some French interpreters to King Ethelbert with an account of their errand, the king gave them leave to convert as many of his subjects as they could, and assigned as their place of residence Durovernum, now *Canterbury*, to which they were confined till the conversion of the king himself, whose example had a powerful influence in promoting the conversion of his subjects; but though he was extremely pleased at their becoming Christians, he never attempted to compel them. Augustin despatched a priest and a monk to Rome, to acquaint the pope with the success of his mission, and to desire his solution of certain questions. These men brought back with them a pall, and several books, vestments, utensils, and ornaments for the churches. His holiness, by the same messengers, gave Augustin directions concerning the settling of episcopal sees in Britain; and ordered him not to pull down the idol temples, but to convert them into Christian churches, only destroying the idols, and sprinkling the place with holy water, that the natives, by frequenting the temples they had been always accustomed to, might be the less shocked at their entrance into Christianity. Augustin resided principally at Canterbury, which thus became the metropolitan church of England; and having established bishops in several of the cities, he died May 26, 607.

Augustine.

AUGUSTINE, (*Aurelius Augustinus*), or AUSTIN, ST, the most illustrious of the fathers of the church, was born at Tagaste (Tajelt), a city in Numidia, on the 13th November, A.D. 354. His father, *Patricius*, was a burgess of Tagaste, and at that time an unconverted pagan; but his mother, *Monica* or *Monnica*, a woman of great piety, instructed their son in the principles of Christianity. In his early youth he fell dangerously ill, and earnestly desired to be baptized; but the danger being past, the rite was deferred. He studied, by his father's desire, at Tagaste, Madaura, and afterwards at Carthage. In his nineteenth year, the perusal of Cicero's *Hortensius* (a work now lost) made a deep impression on his mind, and he began to entertain a love for wisdom. Accordingly he applied himself with diligence to the study of the Sacred Scriptures; but he soon suffered himself to be seduced by the Manicheans, to whose pernicious doctrines he adhered for nine years. After teaching grammar for some time at Tagaste, he returned to Carthage and became a teacher of rhetoric; but being disgusted with his companions and the manners of the scholars, he formed the resolution of going to Rome, much against the inclination of his mother. In that city he soon attracted many scholars; but finding them no less depraved than his former pupils, he quitted Rome and settled at Milan, where he was elected professor of rhetoric. Here he had the opportunity of hearing the discourses of St Ambrose, whose arguments, together with the study of St Paul's epistles, and the conversion of two of his friends, determined him to retract his errors and quit the sect of the Manicheans. He spent the vacation of the year 386 at the country seat of his friend Verecundus, and applied himself in earnest to the study of the Scriptures, preparatory to his baptism, which took place, together with that of his natural son Adeodatus, and his friend Alypius, at Easter in the following year. Shortly after this event, his mother came to Milan, and invited him to return with her to Carthage; but at Ostia, whither they had gone to embark for Africa, Monica was seized with sickness and died. Augustine arrived in Africa towards the close of 388; and having obtained a small villa beyond the walls of the city of Hippo, he associated himself with eleven other persons of eminent piety, and they dwelt together in a monastic state for the space of three years. Renouncing

Augustins || Augustus.

all individual property, they possessed their goods in common, distinguished themselves by wearing leather girdles, and exercised themselves continually in prayer, fasting, study, and meditation. Hence arose the Austin or Augustine friars, or eremites of St Augustine, who were the first order of mendicants; those of St Jerome, the Carmelites, and others, being only branches of that of St Augustine.

It was about this period that Augustine acceded to the urgent solicitations of Valerius, bishop of Hippo, to be ordained a priest; but he still continued to reside with his brethren in their little monastery. In the year 393 he was appointed, though still only a presbyter, to expound the creed before the council of Hippo. Two years after, Valerius, who was very desirous to retain the services of so eminent a person, appointed Augustine his coadjutor or colleague, and succeeded in obtaining his appointment to the bishopric of Hippo, by Megalus, bishop of Calame, who was at that time primate of Numidia. The life of Augustine closed amidst scenes of violence and blood. The Vandals under the fierce Genseric laid siege to Hippo; and during this period of aggravated distress and misery, Augustine breathed his last on the 28th August 430, at the age of 76. The best account of his life is to be found in his own celebrated *Confessions*, in which he has recorded with manly candour the excesses of his early years, and the progress of his conversion to Christianity. His writings are greatly esteemed, and there are many editions of his separate works. The best complete edition is that of the Benedictines in 11 vols. folio, published at Paris, 1679–1700, and reprinted at Paris in 1836–38, in 22 half volumes. Tillemont, in his *Ecclesiastical History*, has devoted a quarto volume of 1075 pages to the life and writings of St Augustine.

AUGUSTINS, or Augustinians, one of the four mendicant orders in the Church of Rome, so called from St Augustine, whose rule they observe. The Augustins, popularly also called Austin friars, were originally hermits, whom Pope Alexander IV. first congregated into one body, under their general Lanfranc, in 1256. Soon after their institution this order was brought into England, where they had about thirty-two houses at the time of their suppression. The Augustins dress in black.

AUGUSTOO, or Augustow, a city in Poland, capital of the woiwodship of the same name, situated on the river Netta, near a lake. It contains about 4000 inhabitants, and has a considerable trade in horses and cattle. It was founded in 1557 by Sigismund II. (Augustus). The woiwodship is the northernmost part of Poland, extending from the Bug to the Niemen, between N. Lat. 52. 40. and 55. 5. E. Long. 21. 20. and 23. 9. Its extent is 6870 square miles, inclosing the greater portion of the lakes of Poland, and many districts of extensive woods, but with some patches of good arable land. It is divided into five obwods or circles, one of which bears the same name.

AUGUSTULUS, Romulus, the last Roman emperor of the West. See Roman History.

AUGUSTUS, Fort, a small fortress seated on a plain at the head of Loch Ness, in Scotland, between the rivers Tarf and Oich.

Augustus, the appellation conferred upon Cæsar Octavianus, the first Roman emperor. Its etymology is not quite certain, but the Greeks always translate it by Σεβαστός, "the Venerable." He was the son of C. Octavius by Atia, a daughter of Julia, the sister of C. Julius Cæsar. An account of his life is given under the article Roman History. The obscure name *Octavius*, as Gibbon observes, he derived from a mean family in the little town of Aricia. It was stained with the blood of the proscription; and he was desirous, had it been possible, to erase all memory of his former life. The illustrious surname of Cæsar he assumed as the adopted son of the dictator, for which reason his name Octavius also was changed into Octavianus; but he had too much good sense either to hope to be confounded, or to wish to be compared, with that extraordinary man. It was proposed in the senate to dignify their minister with a new appellation; and, after a very serious discussion, that of Augustus was chosen from among several others, as being the most expressive of the character of peace and sanctity which he uniformly affected. Augustus was therefore a personal, Cæsar a family distinction. The title of Augustus, which should naturally have expired with the prince on whom it was bestowed, continued to be reserved for the monarch; while the name of Cæsar was more freely conferred on his relations, and, from the reign of Hadrian at least, became appropriated to the second person in the state, who was considered the presumptive heir of the empire. Nero was the last prince who could allege any hereditary claim to the honours of the Julian line. But at his death the practice of a century had inseparably connected the appellation with the imperial dignity, and it has been preserved by a long succession of emperors, Romans, Greeks, Franks, and Germans, to the present time.

Aula || Aungervyle.

AULA is used by Spelman for a court-baron, as by Tacitus and Suetonius for courtiers generally. In some old ecclesiastical writers it signifies the nave of a church, and sometimes a courtyard.

Aula Regia, or *Regis*, a court established by William the Conqueror in his own hall, composed of the king's great officers of state, who resided in his palace, and were usually attendant on his person. This court was regulated by the article which forms the eleventh chapter of Magna Charta, and was established in Westminster Hall, where it has ever since continued.

AULCESTER, or Alcester, a market-town of Warwickshire, at the junction of the Alne and Arrow. It was once a place of some importance, and the residence of several of our monarchs in remote periods. It has a fine old Gothic church. Market-day Tuesday. Pop. in 1851, 2027.

AULERCI, a powerful Gallic people who dwelt between the Seine and the Loire. They were divided into three tribes, viz., the *Eburovices*, the *Cenomāni*, and the *Branovices*. According to Ptolemy, the *Diablintes* were a branch of the same.

AULIC, an epithet given to certain officers of the German empire, who compose a court which decides, without appeal, in all processes entered in or submitted to it.

Aulic, in the Sorbonne and foreign universities, is the ceremony observed in conferring the degree of doctor of divinity. It begins by a harangue of the chancellor, addressed to the young doctor, after which he receives the cap, and presides at the aulic or disputation.

AULIS, the port in the Greek island of Eubœa from which the Grecian fleet sailed to the siege of Troy.

AULUS Gellius. See Gellius.

AUMALE, formerly Albemarle, from the Latin *Alba Marla*, a town of France, capital of a canton in the department of Seine Infer., on the banks of the Bresle, 35 miles N.E. of Rouen. Pop. 2000. The French dukedom of Aumale, originally a county, has belonged since 1675 to princes of the blood. In the English peerage the earldom of Albemarle is at present in the family of Keppel.

AUMONE, Tenure in, in *Law*, a tenure where lands are given in alms to some church or religious house.

AUNCEL Weight, an ancient balance, prohibited by several statutes, on account of the deceits practised by it. It consisted of scales hanging on hooks, fastened at each end of a beam, which were lifted up by the hand. In many parts of England auncel weight signifies meat sold by the hand, without scales.

AUNE, a French measure for cloths, &c.: at Rouen = 1 English ell, at Calais = 1·52, at Lyons = 1·061, and at Paris = 0·95; all now superseded by the *mètre*.

AUNGERVYLE, Richard, commonly known by the

Aunis || Auriflamma.

name of *Richard de Bury*, was born in 1281, at St Edmund's Bury, in Suffolk, and educated at the University of Oxford; after which he entered into the order of Benedictine monks, and became tutor to the Prince of Wales. On the accession of his pupil to the throne as Edward III., he was promoted to various offices of dignity, and was finally made bishop of Durham, as well as lord high chancellor and treasurer of England. He corresponded with some of the greatest men of the age, particularly with the poet Petrach. He was of a most humane and benevolent temper. Every week he caused eight quarters of wheat to be made into bread, and given to the poor; besides distributing large sums whenever he travelled. He founded a library at Oxford for the use of the students, which he furnished with the best collection of books then in England; and appointed five keepers, to whom he granted yearly salaries. He died at his manor of Aukland, 24th April 1345, and was buried in the cathedral church of Durham. He wrote, 1. *Philobiblion*, containing directions for the management of his library at Oxford, and a great deal in praise of learning, but in very bad Latin. 2. *Epistolæ Familiarium;* some of which are addressed to Petrarch. 3. *Orationes ad Principes;* mentioned by Bale and Pitts.

AUNIS, an ancient province of France, now included in the departments of the Lower Charente and Deux Sevres.

AURAY, a small seaport town of France, situated on a river of the same name in the department of Morbihan, 10 miles W. of Vannes. It consists of one handsome street, and is chiefly known for its trade. Pop. in 1846, 3755.

AURELIA (from *aureus*, golden). See CHRYSALIS.

AURELIANUS, LUCIUS DOMITIUS, emperor of Rome, See ROMAN HISTORY.

AURELIANUS, *Cœlius*, a very celebrated physician, born in Numidia, probably towards the end of the third century. He wrote on acute and chronic diseases. Edited by Amman, Amstel. 1709, 4to.

AURELIUS VICTOR. See VICTOR.

AURELIUS. See ANTONINUS, *Marcus Aurelius*.

AUREOLA, in its original signification, signifies a jewel, which is proposed as a reward of victory in some public dispute. Hence the Roman schoolmen applied it to denote the reward bestowed on martyrs, virgins, and doctors, on account of their works of supererogation; and painters use it to signify the crown of glory with which they adorn the heads of saints, confessors, and martyrs.

AUREUS, the standard gold coin of Rome, first struck A.U.C. 546; current value = 25 denarii, or 100 sestertii, equivalent to 17s. 8½d. Forty aurei were made from a pound of gold; but their value was gradually diminished till, under Nero, 45 were made from a pound, and under Constantine, 72.—Hussey, *On Ancient Weights and Money*.

AURICH, a province (Landrosteibezirk) of Hanover, situated on the North Sea, between Oldenburg and Holland. It comprizes the old province of East Friesland. Its area is 870 geographical square miles, and it is divided into 12 amts. Pop. in 1848, 174,355, of whom 118,394 were Lutherans, 50,007 Reformers, 3249 Roman Catholics, and 2254 Jews. See HANOVER. Aurich, its capital, is 12 miles N.E. of Emden, with which it is connected by the canal of Trecktief. The town is well built and has an ancient princely castle, in which the provincial courts now sit; several handsome churches, cavalry barracks, gymnasium, and public library. It is noted for its horse and corn markets, and has a considerable general trade. Pop. 4500.

AURICULAR CONFESSION, in the *Roman Catholic Church*, is a declaration of sins made in private to a priest, for the purpose of obtaining absolution. The scriptural authority for this practice is supposed to be found in Matthew xviii. 18; Acts xix. 18; James v. 16; 1 John i. 9.

AURIFLAMMA, or ORIFLAMME, a standard belonging to the Abbey of St Denis, suspended over the tomb of that saint, which the religious, on occasion of any war, took down with great ceremony and gave to their protector or advocate, to be borne at the head of their forces. Oriflamme is sometimes used to denote the chief standard in any army.

Auriga || Aurora Borealis.

AURIGA, the WAGGONER, a constellation of the northern hemisphere. It contains, in Bode's catalogue, 261 stars.

AURILLAC, a town of France, capital of the dep. of Cantal and of an arrond. of the same name. It is pleasantly situated on the right bank of the Jourdanne, which is here crossed by a handsome bridge. It has tribunals of primary instance and commerce, a communal college, a society of agriculture, arts, and commerce, and a public library of 7000 volumes. Here are to be seen remains of the ancient castle of St Etienne, the church of St Geraud, a Benedictine Abbey, &c. The inhabitants manufacture tapestry, lace, cutlery, paper, leather, &c.; and are great breeders of horses. Pop. of arrondissement in 1851, 96,433; of town, 9886.

AURORA, the Ἠώς of the Greeks, the goddess of the dawn, was the daughter of Hyperion and Theia according to Hesiod, or of Pallas according to Ovid. It was under this name that the ancients deified the light which foreruns the rising of the sun above our hemisphere. Aurora is represented by the poets as ascending from her ocean bed in a flame-coloured chariot, and opening with her rosy fingers the gates of the east, pouring dew upon the earth, and causing the flowers to spring. Nox and Somnus fly before her, and the constellations of heaven disappear at her approach. Her amours with Orion, Cephalus, and Tithonus, are celebrated by the poets; and by Astræus she became the mother of the stars, winds, &c. In the tragic writers, Eos is identified with the day.

AURORA BOREALIS, *Polar Light, Northern Lights*, or *Streamers*, is a beautifully luminous meteor, appearing in the form of beams or rays, and sometimes in that of arches or crowns. The rays are seldom stationary, generally flitting with greater or less velocity throughout the heavens; the arches are sometimes single; sometimes several concentric ones are seen. These lights, or meteoric coruscations, are most brilliant in the arctic regions, appearing mostly in the winter season and in frosty weather. In the Shetland Islands, the *merry dancers*, as they are there and elsewhere called, are the general attendants of clear evenings, and serve to diminish materially the gloom of the long winter nights. They commonly appear at twilight near the horizon, and sometimes continue in that state for several hours without any sensible motion; after which they send forth streams of stronger light, which rise from the horizon in a pyramidal undulating form, shooting with great velocity up to the zenith, assuming columnar and other shapes, and varying in colour from a reddish yellow to the darkest russet. At other times they cover the whole hemisphere with their flickering and fantastical coruscations. On these occasions their motions are amazingly quick, and they astonish the spectator with rapid changes of form. They break out in places where none were seen before, skimming briskly along the heavens; then they are suddenly extinguished, leaving behind a uniform dusky track, which, again, is brilliantly illuminated in the same manner, and as suddenly left a dull blank. Some nights they assume the appearance of vast columns; exhibiting on one side tints of the deepest yellow, and on the other melting away till they become undistinguishable from the surrounding sky. They have generally a strong tremulous motion from end to end, which continues till the whole vanishes. According to the state of the atmosphere, their colours vary. They sometimes assume the hue of blood, on which occasion their appearance is considered portentous. Then the rustic sages become prophetic, and terrify the gazing spectators with the dread of war, pestilence, and famine. This superstition is not peculiar to the northern islands; nor are these appearances of recent date. The

Aurora Borealis. Formerly rare.

ancients called them *chasmata*, and *trabes*, and *bolides*, according to their forms or colours.

In early times, it is said, these meteoric lights were extremely rare, and on that account were the more taken notice of. From the days of Plutarch to those of our sage historian Sir Richard Baker, they were supposed to portend great events, and lively imaginations shaped them into aerial conflicts:

> Fierce fiery warriors fight upon the clouds,
> In ranks, and squadrons, and right form of war.

Dr Halley tells us, that when he observed a great aurora borealis in 1716, he had begun to despair of ever seeing one at all; none having appeared, at least of any considerable extent, from the time he was born until then. But notwithstanding this long interval, it seems that, in some periods, the aurora borealis had been seen much more frequently; and perhaps this, as well as many other natural phenomena, may be subject to periodical changes and variations.

History.

The only thing resembling a distinct history of this phenomenon is that which has been given by the learned Dr Halley, in the *Philosophical Transactions*, No. 347. The first account he gives is of the appearance of what is called by him *burning spears*, which were seen at London on the 30th January 1560. This account is taken from a book entitled *A Description of Meteors*, by *W. F.* D.D., reprinted at London in 1654. The next appearance, according to the testimony of Stow, was on the 7th October 1564. In 1574 also, according to Camden, and Stow above-mentioned, an aurora borealis was observed two nights successively, viz. on the 14th and 15th of November, having much the same appearances as that described by Dr Halley in 1716, and which we now so frequently observe. Again, an aurora was twice seen in Brabant, in the year 1575, viz. on the 13th of February and 28th of September. Its appearances at both these times were described by Cornelius Gemm, professor of medicine in the university of Louvain, who compares them to spears, fortified cities, and armies fighting in the air. After this, Michael Mæstlin, tutor to the great Kepler, assures us, that at Baknang in the county of Wurtemberg in Germany, these phenomena, which he styles *chasmata*, were seen by himself no less than seven times in 1580. In 1581 they again appeared, in an extraordinary manner in April and September, and in a less degree at some other periods of the same year. In September 1621, a similar phenomenon was observed all over France, and described by Gassendus, who gave it the name of *aurora borealis*; yet neither this, nor any similar appearance posterior to 1574, is described by English writers till the year 1707, which, as Dr Halley observes, shows the prodigious neglect of curious matters that then prevailed. From 1621 to 1707, indeed, there is no mention made of an aurora borealis having been seen by any body; and, considering the number of astronomers who during that period were in a manner continually poring over the heavens, we may very reasonably conclude that nothing of the kind really made its appearance until after an interval of eighty-six years. A small one was seen in November 1707; and during that and the following year, the same appearances were repeated five times. The next on record is that mentioned by Dr Halley in March 1716, which from its brilliancy attracted universal attention, and was considered by the vulgar as marking the introduction of a foreign race of princes. Since that time these meteors have been much more frequent. Many of those observed in this island have been described. The following account of a splendid aurora borealis, as seen from the Gosport Observatory on the 7th January 1831, will give an idea of the brilliancy of this meteor, and of its colours, lustres, arches, and beams.

Aurora Boreal. Aurora borealis of Gosport.

"In the afternoon of this day there was a peculiar brightness in the atmosphere near the horizon, for several degrees on each side of the true north point, which indicated the approach of an aurora; indeed we have reason to suspect that it was a faint appearance of one; while the sun shone in all his splendour, without the interposition of cloud or vapour. Shortly after sunset an aurora borealis gradually rose above the northern horizon, and at a quarter past five o'clock it had assumed the form of an arch of refulgent light, ten degrees in height, and seventy degrees in width. From this time till half-past five it continued to increase in the intensity of its light, expanding to the western point of the horizon, and fifty-five degrees to the eastward of north, which made the chord of the aurora a hundred and fifty-five degrees. Now, a bright *flame-coloured* rainbow-like arch, between three and four degrees broad, and pretty well defined at its upper edge, emanated from the curved edge of the aurora to an altitude of thirty-five degrees; and while it remained apparently stationary, a beautiful rainbow-like arch, still more brilliant, formed about ten degrees south of the zenith, by streamers suddenly springing up from the N. E. by E. and W. by S. points of the horizon, and meeting in the zenith, so that these two bows presented themselves at the same time. At thirty-five minutes past five, the latter bow, in some parts four and in others six degrees in width, divided a little to the eastward of its vertex; and the long streamers which formed it passed off gently to the southward in very bright patches, two in the south-east and one in the south-west quarters, like luminous clouds, and continued in sight nearly a quarter of an hour. One of these bright patches nearly covered Orion several minutes. At forty minutes past five another rainbow-like arch, equally wide and bright, was formed by long streamers from about the same points of the horizon, whose point of convergence was the same, and its course through the feet of Gemini, near the Pleiades, through Aries, the square of Pegasus, the head of Equuleus, and the bow of Antinous. It passed off gradually towards the south; and at a quarter before six the planet Mars, then near the meridian, and about forty-five degrees in altitude, rested, as it were, conspicuously on it. At six it had gone far towards the southern horizon, and could scarcely be perceived, leaving the sky unusually clear and bright. By this time the bow over the aurora had much increased in altitude, and was nearly effaced.

"At a few minutes past six, after a great many coloured columns of light had risen from the north-east and north-west quarters, and passed the zenith, the aurora sunk considerably towards the horizon; but its upper edge remained bright and very well defined. Some of the streamers or columns were long, others short, and the widest generally remained long enough to pass through a gradation of prismatic colours. At half-past six the aurora again increased in altitude, and vivid coruscations radiated from every part of its arch, and, on intermixing with each other, formed wide columns, which were so grand with crimson tints as to astonish every spectator. Between seven and eight the aurora had spread at least two thirds over the heavens, and as far as the shoulders of Orion on the eastern side of the meridian, when large perpendicular columns, and short pointed luminous coruscations, rising from the aurora, glittering like spears and conical points in nearly parallel rows, now mixing and then dividing, all passed through red, orange, lake, crimson, green, and purple tints; so that the appearance altogether over so great an extent of the heavens was exceedingly grand, particularly when contrasted with the cerulean sky, and its spangled constellations, in the southern portion of the hemisphere.

Aurora Borealis.

"At ten minutes before eight the aurora was in its greatest splendour. At five minutes before eight another luminous rainbow-like arch stretched across the heavens from the eastern point of the horizon, and displayed several prismatic colours while passing southward. Soon after eight a large dark space, in and near the horizon, presented itself several degrees on each side of the magnetic north, and the aurora, still far over the heavens, gradually diminished. At nine it again ascended, and wide columns rose from every part of its arch, and passed through the same colours as before-mentioned. Between nine and ten the magnetic needle, which in the early part of the evening stood at twenty-four degrees west of the true north, was disturbed, and receded upwards of half a degree northward, either by the influence of the aurora, or by a change of wind from north-east to south-west, and of course a change in its electrical state. At a quarter before eleven there was a grand display of about twelve or fourteen glowing columns from the aurora, several of which passed beyond the zenith, when a perfect red rainbow-like arch, ten degrees above the aurora, was visible. At eleven another bow three degrees and a half wide rose from the aurora, and passed through Aries, Cassiopeia, Ursa Minor, and the square of Ursa Major, until, reaching the zenith, it gradually disappeared. At half-past eleven the aurora again began to sink slowly, and did not rise afterwards. At five minutes before twelve, a large brilliant meteor, the only one observed through the night, passed under Ursa Major. At one o'clock A. M. the highest part of the aurora, about the magnetic north, had sunk to within six or seven degrees of the horizon; yet bright coruscations occasionally emanated from it till two, when the observations were discontinued, as no more interesting meteoric appearances were likely to occur."

Aurora Cumberland House.

The auroras observed, one at Cumberland House and another at Fort Enterprize, in North America, are described by Lieutenant Hood, in Captain Franklin's *Narrative*. The account of the former is as follows:—

"For the sake of perspicuity," says Mr Hood, "I shall describe the several parts of the aurora observed at Cumberland House, which I term *beams*, *flashes*, and *arches*. The *beams* are little conical pencils of light, ranged in parallel lines, with their pointed extremities towards the earth, generally in the direction of the dipping needle. The *flashes* seem to be scattered beams, approaching nearer to the earth, because they are similarly shaped, and infinitely larger. I have called them flashes, because their appearance is sudden, and seldom continues long. When the aurora first becomes visible, it is formed like a rainbow, the light of which is faint, and the motion of the beams undistinguishable. It is then in the horizon. As it approaches the zenith, it resolves itself at intervals into beams, which, by a quick undulating motion, project themselves into wreaths, afterwards fading away, and again brightening, without any visible expansion or concentration of matter. Numerous flashes are seen in different parts of the sky. That this mass, from its short distance above the earth, would appear like an *arch* to a person situated at the horizon, may be demonstrated by the rules of perspective, supposing its parts to be nearly equidistant from the earth. An undeniable proof of it, however, is afforded by the observations of the 6th and 7th of April, when the aurora, which filled the sky at Cumberland House, from the northern horizon to the zenith, with wreaths and flashes, assumed the shape of arches at some distance to the southward.

"But the aurora does not always make its first appearance as an arch. It sometimes rises from a confused mass of light in the east or west, and crosses the sky towards the opposite point, exhibiting wreaths of beams, or coronæ boreales, in its way. An arch, also, which is pale and uniform at the horizon, passes the zenith without displaying any irregularity or additional brilliancy; and we have seen three arches together very near the northern horizon, one of which exhibited beams, and even colours; but the other two were faint and uniform. On the 7th of April an *arch* was visible to the southward, exactly similar to that in the north, and it disappeared in fifteen minutes. It had probably passed the zenith before sunset. The motion of the whole body of aurora is from the northward to the southward, at angles not more than twenty degrees from the magnetic meridian. The centres of the arches were as often in the magnetic as in the true meridian.

Aurora Borealis.

"The *colours* do not seem to depend on the presence of any luminary, but to be generated by the motion of the beams, and then only when that motion is rapid, and the light brilliant. The lower extremities quiver with a *fiery red colour*, and the upper with *orange*. We once saw *violet* in the former. The number of auroræ visible in September was two, in October three, in November three, in December five, in January five, in February seven, in March sixteen, in April fifteen, and in May eleven. Calm and clear weather was the most favourable for observation; but it is discernible in cloudy weather, and through mists. We could not perceive that it affected the weather. The magnetic needle, in the open air, was disturbed by the aurora, whenever it approached the zenith. Its motion was not vibratory, as observed by Mr Dalton; and this was, perhaps, owing to the weight of the card attached to it. It moved slowly to the east or west of the magnetic meridian, and seldom recovered its original direction in less than eight or nine hours. The greatest extent of its aberration was 45′. A delicate electrometer, suspended at the height of fifty feet from the ground, was never perceptibly affected by the aurora; nor could we distinguish its rustling noise, of which, however, such strong testimony has been given to us, that no doubt can remain of the fact."

Aurora of Fort Enterprise.

The account of the aurora observed at Fort Enterprize is also interesting and instructive with reference to the theory of the phenomenon.

"The shapes of the aurora observed at Fort Enterprize, at its entry into the horizon, and progress through the sky, may be reduced under two general descriptions. In the first I shall class those which are formed like rainbows or arches in the earliest stage of their appearance. They rise with their centres sometimes in the magnetic meridian, and sometimes several degrees to the eastward or westward of it. The number visible at the same time seldom exceeds five, and is seldom limited to one. The altitude of the lowest, when first seen, is never less than four degrees. As they advance towards the zenith, their centres (or the parts most elevated) preserve a course nearly in the magnetic meridian, or parallel to it. But the eastern and western extremities vary their respective distances, and the arches become irregularly broad streams in the zenith, each dividing the sky into two unequal parts, but never crossing one another till they separate into parts. Those arches which were bright at the horizon increase their brilliancy in the zenith, and discover the beams of which they are composed when the interior motion is rapid. This interior motion is a sudden glow, not proceeding from any visible concentration of matter, but bursting out in several parts of the arch, as if an ignition of combustible matter had taken place, and spreading itself rapidly towards each extremity. In this motion the beams are formed, such as are described in the preceding observations upon the subject. They have two motions; one at right angles to their length or sideways; and the other a tremulous

Aurora Borealis.

and short vibration, in which they do not exactly preserve their parallelism to each other. By the first they project themselves into wreaths, serpentine forms, or irregular broken curves. The wreaths, when in the zenith, present the appearance of coronæ boreales. The second motion is always accompanied with colours; for it must be observed, that beams are often formed without any exhibition of colours; and I have not, in that case, perceived the vibratory motion. The beams, in different auroræ, and sometimes in the same, are of different magnitudes, arising, probably, from their various distances. These evolutions, often repeated, destroy the shape and coherence of the several arches, though they doubtless retain the arched appearance to the eye of a spectator at the southern horizon; for it would be absurd to suppose that these changes occur only in the zenith of one particular place. The observations at different places in 1820 afford satisfactory proof to the contrary; and the number of arches often increased or diminished in their advance to the zenith, by a dismemberment of which, from their distance, we could not distinguish the particulars. However, their several parts passed gradually to the southward, where they assumed the form of an arch. They are also sometimes distributed into flashes, and other detached portions, which pass to the south-eastward. The revolution of an arch from north to south occupies a space of time varying from twenty minutes to two hours. At Cumberland House, the arches were in many instances almost stationary for several hours, a proof that if their motion was not slower, their distance from the earth was greater, than at Fort Enterprize. The arches, which are faint at the horizon, very frequently pass the zenith without any increase of brilliancy or apparent internal motion.

"The second general class of auroræ are those which propagate themselves from different points of the compass, between north and west towards the opposite points; sometimes also originating in the south-east quarter, and extending themselves towards the north-west. They may be subdivided, like the former, into the distant arches which pass to the southward without much visible change in their appearance, and those which discover beams, and separate at intervals into wreaths, flashes, and irregular segments, exhibiting all the phenomena described above. In explaining the mode by which the two general classes of auroræ are conducted into the horizon, I shall call the motion of the arches, which is in a plane seldom deviating more than two points from the magnetic meridian, the direct motion; and that by which the auroræ propagate themselves nearly at right angles to the magnetic meridian, the lateral motion. Let us suppose a mass of auroræ to be modelled at its birth in a longitudinal form, crossing the meridians at various angles, the whole to be impelled with a direct motion towards the magnetic south, but the parts having different velocities, and each extremity continually removing itself by a lateral motion from the centre, so as to increase the length of the mass. If the centre enter the northern horizon, it will appear like an arch, the real extremities being invisible; and its direct motion will carry it to the southward in that form. But if one extremity first enter the horizon, it will extend itself by its lateral motion to the opposite point, passing, at the same time, by its direct motion to the southward. Of the unequal velocities of the parts, we had many instances, in the direct motion of the arches, by which the centres were often carried from the zenith sixty or seventy degrees to the southward, while the extremities did not materially alter their positions. Nor can this be accounted for by any application of the rules of perspective, because arches exactly similar sometimes changed the bearings of their extremities in proportion to the advance of their centres; and at Cumberland House, on two occasions, the extremities of arches arrived at the east and west points of the compass, while their centres remained only ten degrees above the northern horizon."

Aurora Borealis.

It was for a long time matter of doubt whether this meteor made its appearance only in the northern hemisphere, or whether it was also to be observed near the south pole. But the occurrence of the aurora in the antarctic regions was clearly ascertained by Mr Forster, who, in his voyage round the world with Captain Cook, observed it in the high southern latitudes, though with phenomena somewhat different from those which are seen here. On the 17th February 1773, when the navigators were in latitude 58° south, "a beautiful phenomenon was observed," says Mr Forster, "during the preceding night, which appeared again this and several following nights. It consisted of long columns of a clear white light, shooting up from the horizon to the eastward, almost to the zenith, and gradually spreading on the whole southern part of the sky. These columns were sometimes bent sidewise at their upper extremities; and though in most respects similar to the northern lights (*aurora borealis*) of our hemisphere, yet differed from them in being always of a whitish colour, whereas ours assume various tints, especially those of a fiery and purple hue. The sky was generally clear when they appeared, and the air sharp and cold, the thermometer standing at the freezing point." The accounts of subsequent navigators, particularly Weddell, though given more in detail, differ in no material respect from that just quoted, and therefore need not be cited at length. They prove that this splendid meteor is not confined to the northern, but occurs also in the southern regions of the globe, though with considerable diversity in the accompanying phenomena.

Aurora Australis.

Colour.—The colours of the polar lights are of various tints. The *rays* or *beams* are steel gray, yellowish gray, pea-green, celandine green, gold yellow, violet blue, purple, sometimes rose red, crimson red, blood red, greenish red, orange red, and lake red. Some of the beams appear as if tinged with black, and resemble dense columns of smoke. The *arches* are sometimes nearly black, passing into violet blue, gray, gold yellow, or white bounded by an edge of yellow. The colours are also sometimes vivid and prismatic. Maupertuis describes a very remarkable red-coloured polar light which he saw at Oswer Zornea on the 18th December 1786. An extensive region of the heavens towards the south appeared tinged of so lively a red, that the whole constellation Orion seemed as if dyed in blood. The light was for some time fixed, but soon became movable; and after having successively assumed all the tints of violet and blue, it formed a dome, of which the summit approached the zenith in the south-west. Its splendour was so great as to be in no degree affected by the bright light of the moon. Maupertuis adds, that he observed only two of these northern lights in Lapland, which are of very rare occurrence in that country, although the aurora there assumes a great variety of tints; hence they are considered by the natives as of portentous omen, and as the forerunner of some great calamity. These red-coloured polar lights have of late years been observed in the Shetland Islands; in many parts of Scotland, as in the neighbourhood of Edinburgh; and in England, from its northern to its southern extremity.

Lustre of the Polar Lights.—The lustre varies in kind as well as intensity. Sometimes it is pearly, sometimes imperfectly vitreous, sometimes also metallic. Its degree of intensity varies from a very faint radiance to a light nearly equalling that of the moon.

Progressive Motions.—The reverend James Farquharson states that "the aurora borealis follows a determinate order

Aurora Borealis.

in its appearance and progress; that the streamers or beams generally appear first in the north, forming an arch from east to west, having its vertex at the line of the magnetic meridian; that when this arch is yet only of low elevation, it is of considerable breadth from north to south, having the streamers of which it is composed placed crossways in relation to its own line, and all directed towards a point a little south of the zenith; that the arch *moves forward towards the south,* contracting its lateral dimensions as it approaches the zenith, and increasing in intensity of light by the shortening of the streamers near the magnetic meridian and the gradual shifting of the angles which the streamers near the east and west extremities of the arch make with its own line, till at length these streamers become parallel to that line, and then the arch is seen as a narrow belt, 3° or 4° only in breadth, extending across the zenith at right angles to the magnetic meridian; that it still makes progress southwards; and, after it has reached several degrees south of the zenith, again enlarges in breadth, by exhibiting an order of appearances the reverse of that which had attended its progress towards the zenith from the north; and that the only conditions which can explain these appearances are, that the streamers of the aurora are vertical, or nearly so, and form a deep fringe or arch, which stretches a great way from east to west at right angles to the magnetic meridian, but which is of no great thickness from north to south; and that the arch moves southward, preserving its direction at right angles to the magnetic meridian." The same gentleman elsewhere remarks, that "the whole lights in the north part of the sky made a rapid progress southward; and the manner of this progress was repeatedly finely exhibited in the fringes and fragments that had reached or passed the zenith, by the extinction of streamers at their northern faces, and the formation of new ones at their southern faces. The advanced southern fringe expired when it had reached about 25° south of the zenith; and all did so, either when they attained a similar angle south, or before they had gone so far. The confused mass of streamers in the north, as they came forward in succession to the zenith, and passed that point, unfolded themselves into narrow zones of light at right angles to the magnetic meridian, or very nearly so; for there was occasionally a small deviation from parallelism among themselves. The zones were more numerous than usual, and were separated from each other by less intervals, sometimes not exceeding 3° or 4°, sometimes, however, 15° or 20°." (*Edinb. Phil. Mag.*)

Height of the Polar Lights.—Opinions differ as to the elevation of the aurora borealis above the surface of the earth, which is a point that can be determined only by a series of accurate observations. Dr Halley observed that the aurora described by him rose to a prodigious height, it being seen from the west of Ireland to the confines of Russia and Poland on the east, nor did he know how much farther it might have been visible; so that it extended at least 30 degrees in longitude, and from latitude 50 degrees N. it was seen over all the northern part of Europe; and, what was very surprising, in all those places where it was visible, the same general appearances were exhibited which Dr Halley noticed at London. But he observes, with seeming regret, that he could by no means determine its height for want of observations made at different places; otherwise he might easily have calculated the height of the aurora, as he did that of the luminous ball of 1719. Father Boscovich, says he, determined the height of an aurora borealis, observed on the 16th of December 1737 by the Marquis of Poleni, to have been 825 miles; Bergmann, from a mean of thirty computations, makes the average height of the aurora borealis to be 70 Swedish or upwards of 460 English miles; Euler supposes it to be several thousands of miles in height; and Mairan also assigns it a very elevated region. In the 74th volume of the *Philosophical Transactions* Dr Blagden, speaking of the height of some fiery meteors, remarks that the "aurora borealis appears to occupy as high if not a higher region above the surface of the earth, as may be judged from the very distant countries to which it has been visible at the same time." On the 22d October 1804 it is said that the same polar light was seen at the same time in Saxony and in Liefland. Mr Dalton of Manchester, in a paper read to the Royal Society of London on the 17th April 1828, describes a polar light which he observed on the 29th March 1826, assuming the form of a regular arch at right angles to the magnetic meridian, and continuing for above an hour in the same position; thus affording a favourable opportunity for obtaining the data requisite for determining its height. He took great pains to collect as many authentic accounts as possible of the apparent position of this luminous arch with reference to the stars, when seen from various places where it had been observed in England and in Scotland. And according to Mr Dalton's view of the distribution of the meteor, it appears to have been seen in places 170 miles distant from one another in a north and south direction, and 45 miles distant from east to west, thus comprising an area of 7000 or 8000 square miles; but it must have been visible over a much greater extent. Accounts were received of its having been seen as far north as Edinburgh, and as far south as Manchester and Doncaster, and at most of the intermediate towns. From the exact correspondence of the descriptions at all these places, it was inferred that they referred to the same individual luminous appearance. In proceeding from north to south, the apparent altitude of the arch continually increased, still keeping the south of the zenith to the distance of Kendal, at which place it very nearly crossed the zenith. At Warrington, which is farther south, the culminating point of the arch was north of the zenith; and, wherever seen, the arch always seemed to terminate nearly in the magnetic east and west, at two opposite points of the horizon. The observations in which the author placed the greatest confidence for determining the height of the aurora were those made at Whitehaven and at Warrington, places which are distant 83 miles from each other, and situated nearly on the same magnetic meridian. Calculating from the data they afford, he found the height of the arch very nearly 100 miles above the surface of the earth, and immediately over the towns of Kendal and Kirkby-Stephen. This conclusion is countenanced by observations made at Jedburgh; yet if the former be compared with those at Edinburgh, the height will come out to be 150 or 160 miles, and the position vertical above Carlisle; but he thinks the former result more entitled to confidence. Assuming the height to be 100 miles, it follows that the breadth of the arch would be eight or nine miles; and its visible length, in an easterly and westerly direction from any one place, would be about 550 miles.

But we are disposed to reject these calculations of Dalton, because from the particular details in his memoirs, and the known distribution of the auroræ, it is highly probable that the auroræ said by him to have been seen at the same time at great distances were different auroræ, and then not much elevated above the clouds. Indeed Mr Farquharson, in the *Philosophical Transactions*, part i. 1829, when discussing the value of Mr Dalton's observations, thinks that the observations made from Edinburgh to Warrington might be explained on the supposition that there were several nearly vertical arches of the aurora, almost contemporaneously hanging over many lines from Edin-

Aurora Borealis.

burgh to Warrington, at a few thousand feet above the surface. The observations of Dr Richardson, Captain Franklin, Lieutenant Hood, and others, render it highly probable that many polar lights occur at heights not higher than the region of clouds. Dr Richardson's observations seem to show that the aurora is occasionally seated in a region of the atmosphere, below a kind of cloud which is known to possess no great altitude, namely, that modification of cirro-stratus which, descending low in the atmosphere, produces a hazy sheet of cloud over-head, or a fog-bank in the horizon. Indeed Dr Richardson is inclined to infer that the aurora borealis is constantly accompanied by, or immediately precedes, the formation of one or other of the forms of cirro-stratus. On the 13th of November and 18th December 1826, at Fort Enterprize, its connection with a cloud intermediate between cirrus and cirro-stratus is mentioned; but the most vivid coruscations of the aurora were observed when there were only a few thin attenuated shoots of cirro-stratus floating in the air, or when that cloud was so rare that its existence was only known by the production of a halo round the moon. The natives of the arctic regions of North America pretend to foretell wind by the rapidity of the motions of the aurora; and they say, that when it spreads over the sky in a uniform sheet of light, it is followed by fine weather, and that the changes thus indicated are more or less speedy, according as the appearance of the meteor is early or late in the evening; an opinion not improbable, when it is recollected that certain kinds of cirro-stratus are also regarded by meteorologists as sure indications of rain and wind. Dr Richardson frequently observed the lower surface of nebulous masses illuminated by polar lights; a fact illustrative of the comparatively low situation of these auroræ. Biot, also, in the island of Unst, observed many auroræ that could not be higher than the region of clouds. Captain Franklin in like manner observed low auroræ. "The important fact," says he, "of the existence of the aurora at a less elevation than that of dense clouds was evinced on two or three occasions this night (13th February 1821, at Fort Enterprize), and particularly at 11 hours 50 min., when a brilliant mass of light, variegated with the prismatic colours, passed between an uniform steady dense cloud and the earth, and in its progress completely concealed that portion of the cloud which the stream of light covered, until the coruscation had passed over it, when the cloud appeared as before." Captain Parry, as stated in his third voyage, observed auroræ near to the earth's surface. It is said that while Lieutenants Scherer and Ross and Captain Parry were admiring the extreme beauty of a polar light, they all simultaneously uttered an exclamation of surprise at seeing a bright ray of the aurora shoot suddenly downward from the general mass of light, and between them and the land, which was only three thousand yards distant. The ray or beam of the polar light thus passed within a distance of three thousand yards, or less than two miles, of them. Further, Mr Farquharson observed in Aberdeenshire an aurora borealis not more than four thousand feet above the level of the sea; and he agrees with Richardson, Franklin, &c., in believing that the auroræ occur in a region immediately above that of the clouds, and of course vary in height with the different states of the atmosphere. But although this region was very low on the 20th December 1829, in the polar light seen from Alford, we know that at times it is several miles high, agreeing with the observations of these intelligent travellers. We have frequently seen the aurora when the height of the clouds could not be estimated at less than two or three miles, and at other times not higher than a thousand or fifteen hundred feet.

Position of the Polar Lights.—The arches of the polar lights generally cross the magnetic meridian at right angles; when two or more appear at once tney are concentric, and tend to the magnetic east and west. The beams or streamers in the direction of their length coincide with the plane of the dip of the needle, or nearly so; and each individual streamer is, in fact, parallel to the dipping needle. Dr Richardson thinks he has observed a polarity in the masses of cloud belonging to a certain kind of cirro-stratus approaching to cirrus, by which their long diameters, having all the same direction, were made to cross the magnetic meridian nearly at right angles. But the apparent convergence of such masses of cloud towards the opposite points of the horizon, which have been so frequently noticed by meteorologists, is an optical deception, produced when they are situated in a plane parallel to that on which the observer stands. These circumstances, says Dr Richardson, are here noticed, because, if it shall hereafter be proved that the aurora depends upon the existence of certain clouds, its apparent polarity may perhaps, with more propriety, be ascribed to the clouds themselves which emit the light; or, in other words, the clouds may assume their peculiar arrangement through the operation of one cause (magnetism, for example), while the emission of light may be produced by another, namely, a change in their internal constitution, perhaps connected with a motion of the electrical fluid.

Aurora Borealis.

Magnetic Property of the Polar Lights.—Many years ago philosophers remarked that the magnetic needle was agitated during polar lights; and hence it was inferred that these lights were somehow connected with magnetism. Other observers, again, maintained that these observations must be erroneous, as they could not in any instance perceive the compass affected by the presence of this meteor. But the late observations, of Biot, Hansteen, Gay-Lussac, Kupfer, and particularly of Richardson, Franklin, and Farquharson, have demonstrated that the magnetic needle is affected by the polar lights. As the fact is one of the most curious in meteorology, we shall now state some particulars illustrative of its nature. In Captain Franklin's observations, the horizontal compass was placed in a firm sheltered stand, fixed to the back wall of the house at Fort Enterprize, three feet above the ground, on a northern exposure; and the dipping needle was similarly fixed to the end of the storehouse, at the distance of forty feet. There was no iron near either of them. The house stood on a sand-hill, and there were no large stones in its immediate neighbourhood. The horizontal compass belonged to a small variation transit made by Dollond; and its graduated scale, of one and a half inch radius, was divided into degrees, the degrees counting from north towards west to 360. Each degree was subdivided into 20, and, by the assistance of a magnifying glass, he could read it off accurately to within three minutes. The horizontal position was preserved by means of a spirit-level attached to the instrument.

Action of the polar lights on the compass.

The manner in which the needle is affected by the aurora will require some description. "The motion communicated to it," says Captain Franklin, "was neither sudden nor vibratory. Sometimes it was simultaneous with the formation of arches, prolongation of beams, or certain other changes of form or action of the aurora. But generally the effect of these phenomena upon the needle was not visible immediately, but in about half an hour or an hour the needle had attained its maximum of deviation. From this its return to its former position was very gradual, seldom regaining it before the following morning, and frequently not until the afternoon, unless it was expedited by another arch of the aurora operating in a direction different from the former one.

"The *arches* of the aurora," he adds, "most commonly traverse the sky nearly at right angles to the magnetic

Aurora Borealis.

meridian, but the deviations from this direction, as has been already stated, were not rare; and I am inclined to consider that these different positions of the aurora have considerable influence upon the direction of the needle. When an arch was nearly at right angles to the magnetic meridian, the motion of the needle was towards the west; this westward motion was still greater when one extremity of an arch bore 301°, or about 59° to the west of the magnetic north, that is, when the extremity of the arch approached from the west towards the magnetic north. A westerly motion also took place when the extremity of an arch was in the true north, or about 36° to the west of the magnetic north, but not in so great a degree as when its bearing was about 301°. A contrary effect was produced when the same end of an arch originated to the southward of the magnetic west, viz. when it bore from about 245° to 234°, and, of course, when its opposite extremity approached nearer to the magnetic north. In these cases the motion of the needle was towards the east. In one instance only a complete arch was formed in the magnetic meridian; in another, the beam shot up from the magnetic north to the zenith; and in both these cases the needle moved towards the west.

"The needle was most disturbed on February 13, P. M., at a time when the aurora was most distinctly seen passing between a stratum of clouds and the earth, or at least illuminating the face of the clouds opposed to the observer. This and several other appearances induced me to infer that the distance of the aurora from the earth varied on different nights, and produced a proportionate effect on the needle. When the light shone through a dense hazy atmosphere, when there was a halo round the moon, or when a small snow was falling, the disturbance was generally considerable; and on certain hazy cloudy nights the needle frequently deviated in a considerable degree, although the aurora was not visible at the time. Our observations do not enable us to decide whether this ought to be attributed to an aurora concealed by a cloud or haze, or entirely to the state of the atmosphere. Similar deviations have been observed in the day-time, both in a clear and cloudy state of the sky, but more frequently in the latter case. Upon one occasion the aurora was seen immediately after sunset, whilst bright day-light was remaining. A circumstance to which I attach some importance must not be omitted. Clouds have been sometimes observed during the day to assume the forms of the aurora, and I am inclined to connect with the appearance of these clouds the deviation of the needle, which was occasionally remarked at such times. An aurora sometimes approached the zenith without producing any change in the position of the needle, as was more generally the case; whilst at other times a considerable alteration took place although the beams or arches did not come near the zenith. The aurora was frequently seen without producing any perceptible effect on the needle. At such times its appearance was that of an arch, or an horizontal stream of dense yellowish light, with little or no internal motion. The disturbance in the needle was not always proportionate to the agitation of the aurora, but it was always greater when the quick motion and vivid light were observed to take place in a hazy atmosphere. In a few instances, the motion of the needle was observed to commence at the instant a beam darted upwards from the horizon; and its former position was more quickly or slowly regained according to circumstances. If an arch was formed immediately afterwards, having its extremities placed on opposite sides of the magnetic north and south to the former one, the return of the needle was more speedy, and it generally went beyond the point from whence it first started."

A series of interesting observations on this subject were also made in December 1829, by the reverend James Farquharson, F. R. S., of Aberdeenshire, with an apparatus transmitted to him by the Royal Society of London. This apparatus consisted of a horizontal brass circle, about one foot in diameter, graduated to divisions of ten minutes, and capable of adjustment to a perfect level by means of spirit levels and screwed feet. Concentrically within this divided circle moved a circular horizontal brass plate, its edge touching the divisions, and having at opposite points two verniers, which, by means of attached microscopes, indicated the movements which it made to 60th parts of ten minutes, or 10″. The movement of the plate within the circle was effected by means of a screw. A circular brass needle-box was attached to the surface of the inner plate, and a vertical pointed steel wire for supporting the needle formed the centre. At opposite points in the needle-box were fixed two micrometers, with cross wires in the foci, for adjusting the needle to a level, and observing any change in its direction. The top of the needle-box was a circular plate of ground glass in a brass ring, made to slip easily off and on, and having screwed into its centre a vertical brass tube about eight inches long, for the purpose of suspending the needle with fibres of silk, for measuring the time of its oscillations. A horizontal brass pin, with a minute perforation for the silk near its middle, passed through the vertical tube near its top, and being contrived with several motions, served to adjust the suspended needle, and bring it correctly over the steel point, where its levelling could be completely ascertained. The magnetic needle itself was a rectangular plate about five inches long, half an inch broad, and $\frac{1}{40}$th of an inch thick. An agate cup set in brass admitted of being screwed in either at the narrow or flat side of the needle; and a little fixed ring of brass, with a minute perforation in its top, rising over the cup, admitted of the ready attachment of the silk; so that the needle could be placed on the steel point, or suspended with the silk, with its flat face either vertical or horizontal. This apparatus measured, with great accuracy, very minute changes in the declination of the needle, one so small as 10″ being quite sensible by it.

The observations made with this apparatus, and published in the *Transactions of the Royal Society of London* for 1830, also show, in a most satisfactory manner, that the magnetic needle is actually affected by the presence of the polar lights. They equally prove that the needle is not in every instance agitated by the polar lights, even when they are very brilliant; the oscillations taking place only when the beams or fringes of the meteor are in the same plane with the dip of the needle. But as the needle is affected in those planes only where the fringes or arches are in the plane just mentioned, it is evident that observers in different latitudes may obtain very discordant results in the same evening. The observations collected by Dalton, of the appearance of the aurora of the 29th March 1826, prove that many fringes or arches may be parallel to each other at remote distances; and the observations of the President of the Royal Society, on a luminous arch in Cornwall, 29th September 1828, which appeared simultaneously with a remarkable aurora of many arches extending over the whole of Aberdeenshire, show that the meteor is sometimes active over a space nearly coincident with the extent of the kingdom; and there is reason for believing that it often extends much farther. There might, therefore, be an extensive succession of observations of disturbance and non-disturbance of the needle at the same instant from north to south over many degrees of latitude.

Noises from the Aurora Borealis.—Having, many years ago, both in this country and in the Shetland Islands, heard very distinctly noises proceeding from the polar lights, we

have always given full credit to the statements of those observers who have published accounts of this fact. It is true that late observers, as Scoresby,[1] Richardson,[2] Franklin, Parry, and Hood, never heard such noises, although they do not deny that they may have been heard. Thus Richardson says, "I have never heard any sound that could be unequivocally considered as originating in the aurora; but the uniform testimony of the natives, both Crees and Copper Indians, and Esquimaux, and of all the older residents in the country, induces me to believe that its motions are sometimes audible." Captain Franklin says, "I have not heard the noise ascribed to the aurora, but the uniform testimony of the natives and of the residents in this country induces me to believe that it is occasionally audible." Parry frequently listened for sounds from the polar lights, but never heard any. Lieutenant Hood says (Franklin's *Narrative*, p. 535), "We repeatedly heard a hissing noise, like that of a musket bullet passing through the air, which seemed to proceed from the aurora; but Mr Wentzel assured us that this noise was occasioned by severe cold succeeding mild weather, and acting upon the surface of the snow previously melted in the sun's rays. The temperature of the air was then — 35°, and on the two preceding days it had been above zero. The next morning it was — 42°, and we frequently heard a similar noise. Mr Hearn's description of the noise of the aurora agrees exactly with Mr Wentzel's, and with that of every other person who heard it. It would be an absurd scepticism to doubt the fact any longer, for our observations have rather increased than diminished the probability of it." Muschenbroeck says that the Greenland fishers in his time assured him that they had frequently heard noises proceeding from the aurora borealis. Mr Nairne is confident that he has heard a hissing and whizzing noise when the polar lights were very bright; and Mr Cavallo affirms that he more than once heard a crackling noise from polar lights. Giesecké, who resided so long in West or Old Greenland, says, "the polar lights sometimes appear very low, and then they are much agitated, and a crashing and crackling sound is heard, like that of an electric spark, or the falling of hail." Professor Parrot of Dorpat describes a magnificent polar light he witnessed on the 22d October 1804, from which a crackling and rustling noise proceeded. "We learn from the inhabitants," says Captain Brooke, in his interesting travels through Norway, "with respect to the polar or northern lights, that they had frequently heard the noise that sometimes attends them, which they describe like that of a rushing wind. At Hammerfest they said they were violent, and descended so low that it would appear almost possible to touch them." In a letter from Mr Ramm of Tonset in Norway, addressed to Professor Hansteen, and published in the *Magazin fur Naturwidenskaberne*, Christiana, 1825, we are told that he several times heard a quick whispering noise simultaneously with the motion of the beams of the polar lights. In the same journal, Professor Hansteen says, "The polar regions being in reality the native country of the polar light, we ought to be particularly interested in obtaining any additional information on the natural history of this remarkable phenomenon; and we have so many certain accounts of the noise attending it, that the negative experience of southern nations cannot be brought in opposition to our positive knowledge. Unfortunately, we live, since the beginning of this century, in one of the great pauses of this phenomenon; so that the present generation knows but little of it from personal observation. It would therefore be very agreeable to receive, from older people, observations of this kind, made in their youth, when the aurora borealis showed itself in full splendour. It can be proved mathematically that the rays of the northern lights ascend from the surface of the earth, in a direction inclining towards the south (an inclination which, with us, forms an angle of about 73°). If, then, this light occupies the whole northern sky, rising more than 17° above the zenith, the rays must proceed from under the feet of the observer, although they do not receive their reflecting power till they have reached a considerable elevation, perhaps beyond our atmosphere. It is therefore conceivable why we should frequently hear a noise attending the northern lights, when the inhabitants of southern countries, who see the phenomenon at a distance of many hundred miles, hear no report whatever. Wargentin, in the fifteenth volume of the *Transactions of the Swedish Academy*, says, that Dr Gisler and Mr Hellant, who had resided for some time in the north of Sweden, made, at the request of the academy, a report of their observations on the aurora borealis." To these observations Professor Hansteen adds, that Captain Abrahamson, in the *Transactions of the Scandinavian Literary Society*, has given an account of several observations of noises that were heard proceeding from the northern lights. The professor concludes with stating that he himself knows several persons who have distinctly heard the same sounds; he expresses his surprise that a fact so well established should be called in question; and he relates, with some sharpness, a conversation he once had on this subject with an Englishman, who remarked that the Norwegian tales of noises proceeding from polar lights were akin to the ghost stories of this country.

Theory of the Aurora Borealis.—The theory of this phenomenon is involved in the copious details which have been given under the different foregoing heads; and, indeed, from all that is known, it appears reasonable to infer that it is intimately connected with electricity and magnetism. "The aurora borealis," says Dr Young, "is certainly in some measure a magnetical phenomenon; and if iron were the only substance capable of exhibiting magnetic effects, it would follow that some ferruginous particles must exist in the upper regions of the atmosphere. The *light* usually attending this magnetical meteor may possibly be derived from electricity, which may be the immediate cause of a change in the distribution of the magnetic fluid contained in the ferruginous vapours which are imagined to float in the air." (*Lectures*, vol. i. p. 687.) This assumption of ferruginous particles or vapours, however, seems purely gratuitous and imaginary; and as iron is not the only substance or matter capable of exhibiting magnetic effects, light itself being susceptible of polarization, the above hypothesis is therefore untenable even on the ground on which it has been rested by its author. But it is nevertheless certain that the cause of this luminous meteor is intimately connected with magnetism and electricity; or rather, as the magnetic is variously modified and affected by the electric power, with the phenomena of electro-magnetism. "It is doubtful," says Dr Young in another place, "whether the light of the aurora borealis may not be of an electric nature; the phenomenon is certainly connected with the general cause of magnetism:" and he refers in support of this opinion to the ascertained fact that the primitive beams or rays of light are constantly observed in a direction parallel to that of the dipping needle; adding, that "although the substance be magnetical, the illumination which renders it visible may still be derived from the passage of electricity,

[1] *Arctic Regions, and Journal of a Voyage to the Northern Whale Fishery.*
[2] Remarks on the Aurora Borealis, in Franklin and Richardson's *Journey to the Shores of the Polar Sea.*

Aurora Borealis.

at too great a distance to be discovered by any other test." (*Lectures*, vol. i. p. 716.) The fact is, that in magnetism, the agency of electricity is now clearly made out, and they are shown to stand to each other in the relation of effect and cause, at least in as far as that all the phenomena of magnetism are producible by electricity; but no electric phenomena have ever been hitherto produced by magnetism. (Herschel's *Preliminary Discourse*, p. 93.) Hence the aurora "is certainly connected with the general cause of magnetism," in as far as it is a joint result or effect of the cause by which it is now known that all the phenomena of magnetism are producible; but this connection is one of relation or coincidence merely; and hence it is to the agency of electricity that the phenomena of the aurora are primarily to be ascribed. "This wonderful agent," says Mr Herschel, "which we see in intense activity in lightning, and in a feebler and more diffused form traversing the upper regions of the atmosphere in the northern lights, is present, probably in immense abundance, in every form of matter which surrounds us, but becomes sensible only when disturbed by excitements of peculiar kinds." (*Prelim. Discourse*, p. 329, 330.) Mr Canton, likewise, conceives that the aurora is occasioned by the rapid transition or passage of electrical matter from positive towards negative clouds, throughout the upper region of the atmosphere, where the resistance is the least; but he supposes that the aurora which appears at the time when the magnetic needle is disturbed is not the cause of this disturbance, which he attributes to the heat of the earth, and that it is merely the electricity of the heated air above, disengaged chiefly in the northern regions, where the alteration in the temperature of the air is greatest. Be this as it may, however, the experiment contrived by Mr Canton shows clearly that the phenomena of the aurora are intimately connected with, or rather consequent on, a particular constitution of the atmosphere in regard to density and electricity. If, for example, a glass tube about three feet in length be partially exhausted of air, hermetically sealed, and then applied longitudinally to the prime conductor of an electrical machine, the whole tube will be illuminated from end to end, and this illumination will continue for a considerable time after it has been removed from the conductor. If, again, the tube be drawn through the hand either way, the light will become remarkably intense throughout its whole length; and although a great part of the electricity will be discharged by this operation, the tube will nevertheless emit flashes at intervals, if held by one extremity and kept quite steady; while, if grasped by the other hand at a different place, vivid flashes of light will dart from one end to the other, and continue to be emitted for a considerable time without any fresh excitation. It is to be observed, however, that if the density of the air included in the tube be either increased or diminished beyond a certain limit, none of these luminous appearances will be exhibited; and it is this circumstance which shows that the phenomena of the aurora depend on a certain constitution of the atmosphere in point of density and electricity, and that the meteoric appearances or coruscations can never attain the elevation ascribed to them by some philosophers, but must in every case be confined within the limits of our atmosphere, conformably to the observations of Biot and others already detailed. Beccaria, indeed, conjectures that there is a constant and regular circulation of the electric fluid from north to south; and he gives it as his opinion that the aurora borealis is this electric matter performing its transit southwards, in a state of the atmosphere which renders it visible, or approaching nearer than usual to the earth. But such a transition or circulation as that here suggested could only be produced by the diurnal revolution of the earth round its axis; and as the meteor is observed in the southern with nearly the same appearances as in the northern hemisphere, there must consequently be a circulation from south to north as well as from north to south; in other words, if there be any such tendency as that which Beccaria supposes, it must proceed equally or nearly so from both poles towards the equator. The following is a list of the most important papers, treatises, and works on this subject: *Berlin Mem.* 1710, i. 131; Halley, *Phil. Trans.* 1716, 1719, xxix. 406, xxx. 584; Hearne, *Phil. Trans.* xxx. 1107; Langworth, Huxham, Hallet, and Callendrini, *Phil. Trans.* xxxiv. 132, 150; Maier, *C. Petr.* iv. 121; Mairan, *Traité de l'Aurore Boréale*, 1733, 1754; Weidler, *de Aurora Boreali*, 4; Wargentin, *Phil. Trans.* 1751, p. 126, and *History*, 1752, p. 169, 1753, p. 85; Bergmann, *Schw. Abh.* 200, 251; Wiedeburg, *über die Nordlichter*, 8, Jena, 1771; Hüpsch, *Untersuchung des Nordlichts*, 8, Cologne, 1778; Van Swinden, *Recueil de Mémoires*, Hague, 1784; Cavallo, *Phil. Aurum Coronarium ‖ Ausenses.

AURUM CORONARIUM, in *Roman Antiquity*, a present of money collected in the provinces for a victorious general, which was originally expended for a golden crown (Cic. *Leg. Agr.* ii. 22). The number of crowns sent to a general was sometimes very great. (Liv. xxxix. 7.)

AURUM MUSIVUM, or MOSAICUM, the old name for the bisulphuret of tin. See CHEMISTRY.

AURUNGABAD, a city of Hindostan, in the native state of Hyderabad, or dominions of the Nizam. It was founded about the year 1620 under the name of Gurka, by Mallik Amber, an Abyssinian who had risen from the condition of a slave, to great influence and command. Subsequently it became the capital of the Mogul conquests in the S. of India; and in the time of Aurungzebe, who made it the seat of government during his viceroyalty of the Deccan, it received the name of Aurungabad, and became the principal place of an extensive province of the same name, stretching westward to the sea, and comprehending nearly the whole of the territory now comprised within the British districts, constituting the northern division of the Presidency of Bombay. Aurungabad continued to be the capital of the succession of potentates bearing the modern title of Nizam, after those chiefs became independent of Delhi, until they quitted it for Hyderabad. The city has greatly fallen from its ancient grandeur. The interior is but half peopled, and in ruins, presenting melancholy appearances of desertion and decay. The population is, however, still considerable, and in the bazaar, which is very extensive, are exposed for sale various kinds of commodities, European and Indian, particularly silks and shawls. The walls are similar in their construction to those of all the other cities in this quarter in India, being rather low, with round towers. Distance from Poona 138 miles, from Bombay by Poona 207, from Hyderabad 270. Long. 75. 21. E. Lat. 19. 51. N. (E. T.)

duced to an assembly of the men, who met every three months, and the man to whom any child first spoke acknowledged himself its father. They celebrated annually a feast in honour of Minerva, in which the girls, dividing into two companies, fought with sticks and stones, and those who died of their wounds were concluded not to have been virgins.

AUSONIA, an ancient name of Italy, so called from the Ausŏnes, who were likewise designated Aurunci.

AUSONIUS, Decimus Magnus, a Roman poet of the fourth century, was the son of an eminent physician, and born at Burdigăla (*Bordeaux*) about A.D. 300. His education was conducted with unusual care, either because his genius was very promising, or because the scheme of his nativity, which had been cast by his maternal grandfather, was found to promise great fame and advancement. He made extraordinary progress in classical learning; and after completing his studies at Toulouse, he practised for a time at the bar in his native place. At the age of 30 he became a teacher of grammar, and soon afterwards was promoted to be professor of rhetoric. In this office he acquired so great a reputation that he was appointed preceptor to Gratian, the Emperor Valentinian's son. The rewards and honours conferred on him for the faithful discharge of his duties, prove the truth of Juvenal's maxim,—that when fortune pleases she can raise a man from the humble rank of rhetorician to the dignity of consul. He was appointed consul by the Emperor Gratian in the year 379, after having filled other important offices; for besides the dignity of quæstor, to which he had been nominated by Valentinian, he was made præfect of Latium, of Libya, and of Gaul, after that prince's death. His speech returning thanks to Gratian on his promotion to the consulship, is highly commended. The time of his death is uncertain, but he was certainly alive in 388, and is said to have attained a great age. It has been supposed that he was a convert to Christianity. There is great inequality in his works. His manner and style are often harsh, and he is decidedly inferior to Claudian in Latinity and versification. The best edition of Ausonius' poems is the *Variorum* of Tollius, published in 8vo at Amsterdam in 1671.

AUSPEX, a name signifying "the observer of birds" for the purpose of ascertaining the will of the gods, and is synonymous with *augur*. The word is formed from *avis*, bird, and *inspicere*, to inspect. *Plin. Quæst. Rom.* c. 72.

Ausserhoden ‖ Australasia.

AUSSERHODEN, or Outer Rhodes, one of the districts of the canton of Appenzell, in Switzerland. See Appenzell.

AUSTEN, William, an eminent English artist of the fifteenth century, whose works in bronze are pronounced by Flaxman to equal in style the first Italian *Cinquecentists*. His best-known work, the magnificent tomb of Richard Earl of Warwick, who died in 1439, is in the Beauchamp chapel in that city. It is of gilt bronze, ornamented with many figures in a vigorous style, and displaying great knowledge of the human figure. It is inscribed as the work of "Willm. Austen, citizen and founder of London." See *Dugdale's Warwickshire*.

Austen, *Jane*, an elegant novelist of the present century, born in 1775 at Steventon in Hampshire, of which parish her father was the rector. Miss Austen was a lady of great personal attractions, and a most amiable disposition. Her six novels are pure and spirited delineations of domestic life, with that delicate discrimination of female character which few but of the gentler sex can adequately pourtray. "*Sense and Sensibility*," "*Pride and Prejudice*," "*Mansfield Park*," and "*Emma*," were published before her death; but "*Northanger Abbey*," and "*Persuasion*," were posthumous works. Miss Austen died at Winchester on the 24th of July 1817.

AUSTER, the south wind, or south-west wind, called *Notus*, Nóros, by the Greeks.

AUSTERLITZ, a small town of Moravia, 12 miles E.S.E. of Brunn. It has a magnificent palace belonging to the prince of Kaunitz-Rietberg, and contains 3300 inhabitants. It has been rendered memorable by the great victory obtained in its vicinity, on the 2d December 1805, by the French under Napoleon, over the united forces of Austria and Russia under their respective emperors.

AUSTLE, or Austell, St, a market-town in the hundred of Powder, county of Cornwall. It stands in a district rich in tin and copper mines, and abounding in clay used in the porcelain-clay works in the neighbourhood, as well as in the potteries of Staffordshire. There are also some manufactures of woollen cloths. The church is an ancient structure with a very fine tower and many curious sculptures. Market-day Friday. It is 243 miles from London, and 13 from Truro. Population of town in 1851, 3565.

AUSTRALASIA,

Introductory observations.

In modern geography, the *fifth* great division of the earth's surface.

The learned and intelligent President de Brosses was the first writer who suggested that all the lands and islands in the Austral world should be divided into three portions, corresponding with the three great oceans, the Indian or Ethiopic, the Atlantic, and the Pacific; those in the Indian Ocean and to the south of Asia to be named *Australasia;* those in the two Pacifics, from the multitude of islands, *Polynesia* (a name first used, we believe, by De Barros); and those in the Atlantic to the south of Cape Horn, and the Cape of Good Hope, *Magellanica*. The last, however, became unnecessary, as soon as it was ascertained that the *Terra Australis incognita* had no existence.

The two divisions of Australasia and Polynesia will be found to comprehend, with sufficient convenience, all those islands that cannot with propriety be referred to any of the four continents of the globe. Nor is there any difficulty in drawing a line of separation between these two divisions; though it is not quite so easy to mark the distinct boundary between the Australasian and the Asiatic islands, where they melt into each other, about the equator, at the N.W. extremity of Papua or New Guinea. In a geographical view, the small islands of Waygiou, Salwatty, Batanta, Mysol, and Timorlaut, ought strictly to belong to Australasia; but peopled as they are by Asiatics of the Malay tribe, and under the influence of the Dutch settlements, it may perhaps be more proper, in a moral and political point of view, to consider them as belonging to the Asiatic Islands; more particularly as we shall then have all the Australasian population with very few exceptions, marked with more or less of the African or Negro character. But, in fact, all geographical divisions are and must be to a certain degree arbitrary.

Boundaries.

If, then, we take the equator as the northern boundary from the 132° to the 175° of east longitude; continue a line on the latter meridian to the 55th parallel (bending a little to take in New Zealand) for the eastern; another line along the same parallel to the 65th degree of east longitude for the southern; and a slanting line to the point on the equator from which we set out, so as to include Kerguelen's Land, and pass on the eastern sides of Timorlaut, Ceram, Mysol, and Salwatty, for the western boundary; those lines

Plate C.

Australasia. will circumscribe the whole of the Australasian islands. We have included the uninhabited islands of Kerguelen and St Paul and Amsterdam, because they cannot properly be considered as African islands, though arranged, we believe, under that division by Pinkerton; they are of less importance to geography than to geology.

Australasia, then, may be subdivided into the following groups and islands:—

1. Australia, or New Holland.
2. Van Diemen's Land, or Tasmania.
3. New Guinea, and the Louisiade Archipelago.
4. New Britain, New Ireland, and neighbouring islands.
5. Solomon's Islands.
6. New Hebrides.
7. New Caledonia.
8. New Zealand, and isles to the southward.
9. Kerguelen's Islands, or Islands of Desolation.
10. St Paul and Amsterdam.
11. Numerous reefs and islets of coral scattered over the Australasian Sea.

Australia, or New Holland. I. The first attempt to explore this island, which, from its size, may be considered as the fifth continent of the earth, is unquestionably due to the Dutch; for although some part of the northern coast may have been seen by the early navigators of Spain and Portugal, there is no direct testimony in favour of such a discovery. There are two charts in the British Museum which belonged to the *Harleian Collection;* one French, without date, which was probably the original; and the other English, apparently a copy: the latter is dedicated to the king of England, and bears date 1542. In both of these charts is marked down an extensive tract of country to the southward of the Moluccas, under the name of *Great Java*, agreeing more nearly with the position and extent of New Holland than any other land. The form given to the N.W. part of the coast in these charts approaches nearest to the truth; a part, indeed, which may have been seen by those early navigators who visited the Moluccas long before the date of the English chart. It is a singular coincidence in geographical nomenclature, that, on the east coast of the French chart, something like a *Botany Bay* should be designated under the name of *Coste des Herbaiges.* The Abbé Prévost, in the *Histoire Générale des Voyages*, and the President de Brosses, in his *Histoire des Navigations aux Terres Australes*, are not very happy in advancing a claim in favour of Paulovier de Gonneville, a French captain, to the discovery of this *Terra Australis* in 1504. It was the coast of Madagascar upon which Gonneville was driven, as is evident by their own accounts.

Progress of discovery.

The best and most authentic abstract of the Dutch discoveries on the coasts of New Holland is contained in the instructions given by the governor-general of Batavia to Commodore Abel Jansen Tasman, and published by Mr Dalrymple in his *Collection concerning Papua.* From this document it appears that the Dutch government of Bantam in 1605 despatched the Duyfhen yacht to explore the islands of New Guinea. Returning to the southward along the islands on the northern side of Torres Strait, she came to that part of the *Great South Land* which is now called Cape York; but all these lands were then thought to be connected, and to form the southern coast of New Guinea. "Thus," says Captain Flinders, "without being conscious of it, the commander of the Duyfhen made the first authenticated discovery of any part of the *Great South Land*, about the month of March 1606." About the same place, and in the same year, Torres, a Spanish navigator, being second in command to Fernandez de Quiros, saw the *Terra Australis*, but had as little knowledge of the nature of his discovery as the commander of the Duyfhen. He passed the strait, however, which divides this *Terra Australis* from New Guinea, whose existence was not generally known till 1770, when it was rediscovered and passed by our great circumnavigator Captain Cook. Of this, and his other discoveries, Torres addressed an account to the king of Spain, and, as it afterwards appeared, had taken the precaution to lodge a copy of it in the archives of Manilla; for, when that city was surrendered to the British forces in 1762, Mr Dalrymple snatched from oblivion this interesting document of early discovery, and, as a just tribute to the enterprising Spanish navigator, he gave to this passage the name of *Torres Strait*, by which it is now universally known. Australasia.

In 1617 the Dutch sent a second expedition, but "with little success;" the journals of which were lost. In 1623, the yachts Pera and Arnheim were despatched from Amboyna, under the command of Jan Carstens, who, with eight of the Arnheim's crew, was treacherously murdered by the natives of New Guinea; but the vessels prosecuted the voyage, and discovered the great islands Arnheim and the Spult. The Arnheim returned to Amboyna; the Pera persisted, and ran along the west coast of New Guinea, as they thought, but in reality New Holland, to Cape Keer-weer or Turn-again, and from thence explored the coast farther southward, as far as 17°, to Staten River. "In this discovery were found everywhere shallow water and barren coasts, islands altogether thinly peopled by divers cruel, poor, and brutal nations; and of very little use to the (Dutch East India) Company."

The next expedition sent by the Dutch was from Banda in 1636, when Gerrit Tomaz Pool proceeded with the yachts Klein Amsterdam and Wesel, and nearly at the same place, on the coast of New Guinea, met the same fate which had befallen Carstens; but the supercargo, Pieterson, continued the voyage, and discovered the coast of Arnheim, or Van Diemen's Land, in 11° S., and sailed along the shore 120 miles, but without seeing any inhabitants.

Abel Jansen Tasman sailed on a second voyage of discovery from Batavia in 1644; but no account of this voyage was ever made public, nor is it known to exist. No chart bearing his name is now known, but there is little doubt that the N.W. coast of New Holland was first explored by him; and it is singular enough that Dampier should say he had Tasman's chart of it. Tasman is also supposed to have sailed round the Gulf of Carpentaria; an opinion which Captain Flinders considers to be strengthened, from the names of Tasman, of the governor-general, and of two of the council, who signed his instructions, being applied to places at the head of the gulf, as well as that of Maria, the governor's daughter, to whom Tasman is said to have been attached. Tasman had sailed, on a former voyage, from Batavia in 1642, for the Mauritius; whence steering south and eastward upon discovery, he fell in with land, to which he gave the name of *Anthony Van Diemen's Land*, in honour of the governor-general, "our master," he adds, "who sent us out to make discoveries."

The last voyage undertaken by the Dutch for the discovery of *Terra Australis* was in 1705, when three Dutch vessels were sent from Timor, "with orders to explore the north coast of New Holland better than it had been done before." The account, however, given by the President de Brosses is so vague and imperfect that very little satisfactory information is to be obtained from it. It is on the west coast that the Dutch appear to have been most successful. In Tasman's instructions it is stated, that "in the years 1616, 1618, 1619, and 1622, the west coast of this great *unknown* south land, from 35° to 22° south latitude, was discovered by outward-bound ships, and among them, by the ship *Endragt.*" Dirk Hartog commanded this ship, and seems to have made the coast in latitude about 26° 30′ S., and to have sailed northward along it to about 23°, giving the name of *Landt van Endragt* to the coast so discovered; and that of Dirk Hartog's Road (called afterwards *Shark's Bay* by Dampier) to an inlet on the coast a little to the southward of 25°. A plate of tin was found in 1697, and again seen by

Australasia. Baudin in 1801, on one of the islands which forms the roadstead, bearing an inscription that the ship Endragt of Amsterdam arrived there on the 25th October 1616. After this several outward-bound ships fell in by accident with different parts of this coast.

The Dutch made little progress in any other part of the extensive coasts of New Holland. The instructions to Tasman say, "In the year 1627 the south coast of the Great South Land was accidentally discovered by the ship the Guldee Zeepard, outward bound from Fatherland for the space of 1000 miles." From the circumstance of this ship having on board Pieter Nuyts, who was sent from Batavia as ambassador to Japan, and afterwards appointed governor of Formosa, the name of *Nuyts' Land* was given to this long range of coast.

The first English navigator who appears to have seen any part of New Holland is the celebrated William Dampier, who, in his buccaneering voyage round the world, in January 1686, touched at the N.W. coast, for the purposes of careening his vessel and procuring refreshments. He made the land in latitude 16° 15′, and ran along the shore to the N.E. till he came to a bay or opening fit for the purpose. In 1699 Dampier a second time visited the north-western coast of this *Terra Australis*, being now legitimately employed in making discovery in His Majesty's ship the Roebuck. Of this part of the coast little more is yet known than what has been described by Dampier, and that little is due to the exploration of Captain King.

It was left for our celebrated navigator Captain Cook to complete the grand outline of the fifth continent of the world. The reign of George III. will ever be distinguished for the liberal principles on which voyages of discovery were undertaken, and their results communicated to the world. The Endeavour was fitted out to observe, at Tahiti, the transit of Venus over the sun's disk; on her return, in 1770, Captain, then Lieutenant Cook, explored the whole E. coast of the *Terra Australis Incognita*, from Cape Howe to Cape York, not minutely entering into the details of every part, which would have been impossible, but laying down a correct general outline. "He reaped," says Captain Flinders, "the harvest of discovery; but the gleanings of the field remained to be gathered." In his passage through Endeavour Strait, between Cape York and the Prince of Wales' Islands, he not only cleared up the doubt which till then existed, of the actual separation of *Terra Australis* from *New Guinea*, but, by his accurate observations, enabled geographers to assign something like a true place to the former discoveries of the Dutch in these parts.

In 1777 Captain Cook, in the Resolution and Discovery, visited Van Diemen's Land; but as Captain Furneaux, in His Majesty's ship Adventure, had preceded him four years, and Tasman and Marion had examined the coast, little was here supposed to remain for discovery, except in detail. It was long subsequent to Furneaux's visit that Van Diemen's Land was ascertained to be an island; a discovery which may have been retarded by that officer having given an opinion "that there is no strait between New Holland and Van Diemen's Land, but a very deep bay." The existence of such a strait was, however, suspected; but the various attempts to ascertain it, without success, by different navigators from both sides of the coast, seemed to have decided the question in the negative, when Mr Bass, surgeon of the Reliance, having observed, as he ran down the E. coast in an open whale boat, that a heavy swell rolled in from the westward, was satisfied in his own mind that such a swell could proceed only from the great Southern Ocean. To ascertain whether this was the fact, was a point of great importance to the new colony on the eastern coast; and for this purpose Mr Flinders, together with Mr Bass, was sent on this service in a small decked boat. At the end of three months they returned to Port Jackson, with an interesting account of the survey of the coasts of Van Diemen's Land, which they had completely circumnavigated, and thus confirmed the conjecture of Mr Bass, whose name the strait deservedly bears. Australasia.

The French are entitled to the honour of some partial discoveries on *Terra Australis*. Captain Marion, in the year 1772, was despatched from the Isle of France with two ships, the Mascarin and Marquis de Castries, on a voyage of discovery, one of the objects of which was that of the supposed southern continent. He touched at Van Diemen's Land, quarrelled with the natives, and finding no fresh water, and the weather being stormy, he set sail for New Zealand, having added very little to the prior discoveries of Tasman.

In the year 1792, Rear-Admiral D'Entrecasteaux, having been sent out with two ships, La Recherche and L'Esperance, in search of the unfortunate La Pérouse, made the S. coast of New Holland, which he explored as far as the Termination Island of Vancouver; the deficiencies of whose chart he was able to supply, by the state of the weather permitting him to keep the coast closer on board than the English navigator had been able to do. Termination Island was found to be the first of a large group laid down by Nuyts, whose accuracy is praised by the Admiral, he having found "the latitude of Point Leeuwin and of the coast of Nuyts' Land laid down with an exactness surprising for the remote period in which they had been discovered." This liberal acknowledgment did not, however, prevent him from giving to the group of islands, which he only saw, but did not survey, the name of *Archipel de la Recherche*. But the most important discovery of D'Entrecasteaux was an inlet on the S. coast of Van Diemen's Land, which was found to be the entrance into a fine navigable channel, running more than thirty miles to the northward, and there communicating with Storm Bay; containing a series of excellent harbours, or rather one continued harbour the whole way, from beginning to end. "The charts," says Captain Flinders, "of the bays, ports, and arms of the sea, at the S.E. end of Van Diemen's Land, constructed in this expedition by Messieurs Beautemps, Beaupré, and assistants, appear to combine scientific accuracy and minuteness of detail with an uncommon degree of neatness in the execution. They contain some of the finest specimens of marine surveying, perhaps, ever made in a new country."

In 1800 Captain Baudin was sent out with two armed vessels, Le Géographe and Le Naturaliste, on a voyage of discovery nominally *round the world*, but actually, as appears from his instructions, to examine every part of the coasts of New Holland and Van Diemen's Land. The first volume of the account of this voyage was published by M. Péron, one of the naturalists, in 1807; the second never appeared. All the old names of the capes, bays, inlets, and islands, were unblushingly changed to those of Napoleon, his family, his marshals, and members of the Institute; and to 900 leagues of the southern coast, comprehending all the discoveries of Nuyts, Vancouver, D'Entrecasteaux, Flinders, Bass, and Grant, was given the general name of *Terre Napoleon*, while not 50 leagues of real discovery were effected which had not been anticipated by Captain Flinders, who, after losing his ship, and proceeding homewards, was scandalously detained as a prisoner in the Isle of France, "to give time for the previous publication of the voyage of M. Baudin, to prepossess the world that it was to the French nation only the complete discovery and examination of the south coast of Australia was due."

Flinders, however, ultimately triumphed. After an unjust and cruel captivity of seven years, he arrived in England in 1810, and in 1814 published his discoveries in two volumes, accompanied with an atlas of charts, which may be regarded as models in maritime surveying. At this time not a single chart of coast, bay, or island, of Captain Baudin's discoveries had appeared, though shortly afterwards an atlas was published by Freycinet, the first lieutenant, differing in their form

Australasia.

and structure very little from those of Captain Flinders, but bearing the names recorded in M. Péron's first volume. The frontispiece to this atlas affords an instance of that almost impious adulation which Buonaparte was in the habit of receiving from his creatures. An *eye*, having an N within it, darts its rays through a dark cloud overshadowing a globe with the southern pole uppermost, on which is drawn the outline of New Holland, with this inscription, "*Fulget et ipso.*"

To Captain Flinders we owe the completion in detail of the survey of the coasts of New Holland, with the exception of the W. and N.W. coasts, which he was prevented from accomplishing by the loss of his ship. To him also, we are indebted for the very appropriate name of "Australia," which is now universally adopted to designate the entire island-continent, instead of the old Dutch name of New Holland. Dampier had said, in anchoring near the south end of De Witt's Land, behind Rosemary Island, which was one of an extensive cluster, "by the tides I met with a while afterwards, I had a strong suspicion that there might be a kind of archipelago of islands, and a passage possibly to the S. of New Holland and New Guinea, into the Great South Sea eastward;" but whether it might be a channel or strait, or the mouth of a large river, he seems not to have made up his mind. Vlaming saw an opening 12 miles wide near the same place, and could find no anchorage. It has now been ascertained that there is no outlet into the Great Ocean eastward, nor into the Gulf of Carpentaria, nor into Bass Strait; but the geographical problem yet remains to be solved, whether the opening in the coast behind Rosemary Island be not the mouth of a large river. Le Géographe and Le Naturaliste, under Baudin, stood along this coast, examined in a very slovenly manner some particular points, but assisted geography less than they perplexed it, by unwarrantably changing every old name for that of some of the upstarts created by the French revolution.

In 1829, when the settlement at Swan River was effected under the governorship of Captain Stirling, R.N., it was expected that our knowledge of the harbours and rivers on the W. coast of Australia would be considerably enlarged. In this expectation, however, geographers were much disappointed, no naval discoveries of any importance having been accomplished under the auspices of the government. It was not until 1837 that the anchorages and harbours in the immediate vicinity of the settlement were correctly laid down; in which year detailed charts of the coast from King George's Sound to Melville Harbour were furnished to the colonial government by J. C. Wickham, commander of H.M.S. Beagle. That excellent officer was intrusted with the duty of conducting a minute survey of all the Australian coast which Flinders had left unsurveyed. He was succeeded in 1839 by Mr Stokes, who continued zealously employed in this important duty until 1843; assisted by a staff of meritorious and scientific officers. The result of their investigations was not only a considerable addition to natural history, but a complete topography of the bays and harbours on the N.W. and northern coasts; besides the important discovery of four rivers of considerable magnitude. The largest of these, the Victoria, flows into Cambridge Gulf in Lat. 16°, which Stokes explored towards its source for a distance of 140 miles. He also discovered in Torres Strait a safe channel through the inner passage, at the extreme N. of this vast territory; while at the extreme S. he rendered the charts of Bass's Strait as safe for the mariner to navigate by, as those of the English Channel. Having circumnavigated the island, he and his predecessor left no harbour or estuary unsurveyed, which previous navigators had passed over; and doubtful positions of capes and other headlands they finally assigned to their correct latitudes and meridians upon the map. The detailed outline of the Australian coasts may now therefore be considered as complete, so far as maritime discovery is concerned. It is from the interior that we must look for further explorations of the many streams which are known to flow into the bays on its extensive shores.

Australasia.

For 25 years after the settlement was effected at Sydney, the Blue Mountains, which are visible from the heights around Port Jackson, formed the barrier to the government surveyors in their explorations to the westward. And it is a fact which serves to illustrate the difficulties which beset the progress of the Australian explorer, even at the present day, that during this period all the country beyond the inlets and their ramifications on the coast, and the course of the Hawkesbury River in the interior,—a semicircular section of land about 50 miles across, and comprised within the present county of Cumberland,—was a complete *terra incognita* to the settlers. This range of mountains, which forms a section of the great Australian Cordillera, was at last surmounted by Mr Evans, a government surveyor, and a path found through the forest in 1813. This discovery led to the occupation of the pastoral lands to the westward; since known to all the world as the Bathurst gold-fields. Three enterprising colonists named Wentworth, Lawson, and Blaxland, were the first to occupy that region with their flocks and herds. They ascertained that it was not only better watered, and had more permanent running streams than the country on the eastern flank of the main range, but possessed a cooler climate, with richer alluvial soils, and was altogether better adapted for agricultural operations than the poor lands and warm climate nearer the coast. Forty years have since then elapsed; and not only has that western country become densely peopled on every side, and a road carried over the mountains, but even in the trackless wilds of the interior, intrepid men, braving all hardship and peril, have explored the recesses of this vast continent.

Explorations in the interior.

Of these explorations it will be necessary to give a brief abstract. In 1813 Mr Evans prosecuted two successful journeys across the Blue Mountains, to the distance of about 300 miles W. from Sydney. As he ascended the range towards the sources of the eastern streams, he came upon the Fish River, to which he gave its name in consequence of the great number of fish his party caught in it; and descending on the western shed of waters he traced the course of the Macquarie River through the Bathurst plains. He was surprised also to find fish of a large size resembling trout in this river, some weighing as much as fifteen pounds. On the plains, unusually large herds of kangaroos were met with, besides numbers of emus. Some aboriginal women and children whom he encountered, were so terrified at the appearance of the white men, that they fell down with fright. Governor Macquarie, who subsequently visited the plains, considered them an eligible site for a township and the centre of a district. He accordingly planned out the present town of Bathurst, by the banks of the river.

Evans, 1813.

In May 1815 Mr Evans was despatched a second time across the Blue Mountains to follow the course of the Macquarie River still further into the interior. On this occasion he traced it for about 115 miles from its source, and then returned; reporting as his opinion that the river crossed the entire breadth of the island to its north-western extremity, a distance of 2200 miles in a straight line. This is an instance of the erroneous speculations of surveyors as to the course of unexplored streams, of which another example was lately given by Sir T. L. Mitchell, with regard to the Victoria. Had Mr Evans pursued his survey about as far again as he had gone, he would have found that his supposed Australian Mississippi lost itself entirely in a marshy plain.

Evans, 1815.

In 1816 Mr Oxley the surveyor-general of the colony, in penetrating into the interior across the Bathurst plains in a S.W. direction, came upon a fine flowing stream which he named the Lachlan; and which has since been found to be one of the great tributaries of the Murray. He followed its course down to 34° S. Lat., and 145. 20. E. Long., and

Oxley, 1816.

Australasia.

traversed the undulating prairie lands to the southward; besides exploring the western flank of the Peel range, or Coccopara Mountains. On his return in January 1817, he recrossed the river in Long. 147. 15. E., and encamped in Wellington valley, through which the Macquarie runs. From thence he traced that river down its course for about 190 miles, where he found it disappear in what is now termed the marshes of the Macquarie; although scarcely 20 miles before it terminates it is a clear flowing river 50 yards wide, and from 7 to 16 feet deep. Retracing his steps, Oxley struck right across the country in an easterly direction from Mount Harris, Lat. 31° S., until he reached the sea-coast. In this journey he encountered many obstacles; and at one time his progress was arrested by the dense vegetation, when he entered the impenetrable country on the western side of the great dividing range. He succeeded, however, in crossing to the eastern waters, when he came upon the Hastings River, which he traced to its outlet at Port Macquarie, about 200 miles N. from Port Jackson.

Explorations in the interior.

That part of the Bathurst country traversed by Evans and Oxley was but thinly peopled. The natives were the same as those of Sydney, but more docile; they wore their kangaroo and opposum-skin rugs with the fur inside, indicating a colder region at that altitude, which averages about 1800 feet above the level of the sea. They exhibited the usual terror of savages at seeing a man on horseback for the first time, imagining Mr Evans and his horse to be one animal. Beyond Bathurst plains, the country was even superior to that first explored. The grassy undulating downs showed a fertile soil; while the kangaroos and emus flocked in hundreds over the sward. A saccharine exudation from the trees, resembling manna, attracted Mr Evans's attention. He also passed mountains composed entirely of blue limestone, and picked up topazes, rock-crystals, and agates, on the very same streams and hills where the gold-fields are now worked.

Oxley, 1823.

In 1823 Mr Oxley was despatched to make a survey of Moreton Bay, 500 miles N. from Sydney. He found several considerable streams flowing into the bay; the largest he named the Brisbane, after the governor then in office. This river is navigable for 60 miles, and presents one of the finest deep-flowing streams on the eastern coast. Proceeding further N. he entered Hervey Bay, and explored Port Curtis, where he found a considerable stream, which he named the Boyne.

Hovell and Hume, 1824–5.

In 1824-5 explorations were actively pursued to a like distance southward. Messrs Hovell and Hume, two enterprizing settlers, who had driven their live stock over the ranges to fresh pastures on the Yass Plains—through which the present road from Sydney to Melbourne passes—animated by the spirit of discovery, pushed on, single-handed, to explore the southern regions. During their journey they passed over a most extensive range of country from the junction of the Murrumbidgee and Yass Rivers to the western shore of Port Phillip. They were the first travellers who crossed the main branch of the greatest known Australian river, which was deservedly named by the colonists after Mr Hume. On its further exploration, however, by Captain Sturt in 1830, when he descended to its termination in a boat, that gallant officer named it the Murray, in compliment to Sir George Murray, who presided over the colonial office at that time.

Cunningham, 1825.

In 1825 the indefatigable but unfortunate botanist, Allan Cunningham, prosecuted a successful exploration up the valley of the Hunter, and through a gap in the Liverpool ranges, which he called Pandora Pass; where he discovered a fine country, through which a western stream flowed in a northerly direction. In 1827 he crossed the same range of mountains at the source of the N. branch of the Hunter River, and travelled in a northerly direction over the beautiful table-land known as the Liverpool Plains. Continuing his course a little more to the eastward of that region. he traversed a fine grazing country at the elevation of 1500 feet above the level of the sea, which he called New England. Farther N. still, he discovered the verdant prairie-lands of Darling Downs, proceeding onwards until he reached the Lat. of 28. 10. S., having discovered a greater extent of grazing land in New South Wales than any explorer before or since. Making a detour to the eastward, he ascertained the direction of the great dividing range, and retraced his steps. During the following year, and in 1829, he proceeded to Moreton Bay, and prosecuted a successful journey to the source of the River Brisbane. He likewise discovered a pass on the E. side of the range which divides Darling Downs from Moreton Bay district.

Australasia.

Explorations in the interior.

Sturt, 1828–9.

In 1828-9 Captain Sturt travelled from Wellington Valley, along the banks of the Macquarie River, and skirted the marshes which absorb that stream—the same which Oxley had deemed interminable—until he found an open and verdant country to the N.W., with several small streams flowing in that direction. Continuing his course westward, he ascended "New Year's Range," and descried some high table-land and grassy plains to the N.W. His further researches were rewarded by the discovery of the Darling, the greatest tributary of the Murray; its source being within tropical Australia. Having ascertained the course of this important river, which he followed down as far as 30. 20. S. Lat. and 145. 40. E. Long., he returned, impressed with the idea that it, as well as all the western streams, flowed into an inland sea; a favourite hypothesis of geographers at the time.

With a view to determine this point, and the course of the Murrumbidgee River, or the outlet of its waters, this enterprising officer started a second time in January 1831; and the result has been, that instead of the Darling and the Lachlan, and other streams that run to the westward, falling into a great inland sea or extensive marsh, as was conjectured, their united waters constitute a large river, which, under the name of Murray, was found to turn to the southward, and empty itself into an extensive estuary, 60 miles in length, by 30 or 40 in width. The river, near the point where it fell into this lake or estuary, was about 400 yards wide and 20 feet deep. The whole country on both banks was composed of undulating and picturesque hills, at the bases of which extended plains and valleys, within sight of many thousand acres of the richest soils.

The mouth through which the waters of the estuary communicated with the sea was in Encounter Bay, in Long. 139. 40. E. and Lat. 35. 25. 15. S., a little to the eastward of the Gulf of St Vincent, and round the point named Cape Jervis. The river was well stocked with fish, and its banks more populous than any other part of the country that had been traversed. Some accounts state the total number of aborigines seen to have amounted to at least 4000. They could scarcely be brought to believe that the discovering party were of the same genus as themselves; they placed their hands against those of the strangers, in order to ascertain if the number of fingers on each corresponded. Nothing surprised them more than the act of taking off the hat, believing, it would seem, that the superstructure of *felt* formed a part of the strange animal that had come into their country.

Banister, 1831.

In 1831, while these explorations were opening up a knowledge of Eastern Australia, the government of the new colony of Swan River in Western Australia, despatched Captain Banister to explore the country between that settlement and King George's Sound. This journey he accomplished at the risk of death by starvation to himself and his party. He has represented the country he passed through as of the most inviting description for settlers, both for grazing and agriculture. Several other expeditions were subsequently prosecuted to the N.W. of that territory by

Australasia.

Captain Grey and others, which added much information concerning the coasts and bays up to that time visited only by Tasman, Dampier, Baudin, and King.

Explorations in the interior. Mitchell. 1832.

In 1832 Major (now Sir Thomas L.) Mitchell, surveyor-general of the colony, was instructed by the government to proceed on a journey of discovery to the N.W. of Liverpool Plains, in search of a great stream reported by a captured bushranger to exist in that direction. No such river could be discovered. The party, however, explored a large tract of indifferent country on the upper branch of the Darling River, which, no doubt, was the great stream of the bushranger, called by him the Karaula. The ability and energy displayed by Major Mitchell in this expedition, induced the government to fit out an exploring party under his command upon an extensive scale, having for its object the thorough survey of the Darling and its tributaries. The expedition

1835. started from Bathurst in 1835, more fully equipped for the journey than any which had started previously in the colony. Major Mitchell was ably seconded in his scientific arrangements by the assistance of the botanist Allan Cunningham. Within a few weeks, however, of their departure, that estimable man fell a sacrifice to his scientific enthusiasm. While the leader and his men were surveying the Bogan River in about Lat. 32. S., he was lost from the main body of the party in his ramblings for plants through the interminable wilderness; and from subsequent facts which came to light, there is every reason to believe that he was murdered by the natives. In memory of his sad fate and invaluable services to the colony, the government have erected an obelisk in the Botanic Garden at Sydney. Major Mitchell reluctantly left the spot where his companion had been missed, and traced the Bogan River down to its confluence with the Darling. Below this junction he erected a stockade which he called Fort Bourke, and from thence surveyed the Darling as far as Lat. 32. 34. S. The fort he found useful as a resting-place on his return homewards.

1836. In 1836 Major Mitchell accomplished a still greater journey into the interior from Bathurst; he followed the course of the Lachlan along its northern bank. After surveying its junction with the Murrumbidgee, and tracing the latter stream to its confluence with the Murray, as previously explored by Sturt, he followed that river in its N.W. course till he found its clear waters mingling with the turbid stream of the Darling, in Lat. 34. 10. From this point he traced the Murray River upwards, crossing the stream to its southern bank a short distance below its junction with the Murrumbidgee; after which he continued surveying upwards to Lat. 36. S. From this point he left the Murray and its tributaries, and journeyed in a S.W. direction across several small streams which he found flowing to the N. In Lat. 37. 10. he came upon a considerable stream flowing to the S. This river he navigated in a canvas boat down nearly to its outlet in the sea; and named it the Glenelg River (in honour of the colonial secretary, Lord Glenelg), which will be found on the map to be situated in Victoria, crossing the boundary between that colony and South Australia, and disemboguing itself into the sea a few miles farther to the west. After surveying this outlet he proceeded eastward towards Portland Bay; and was surprised on his journey thither to encounter two gentlemen driving "tandem" through the beautiful forest lands as leisurely as if they had been in Hyde Park, where he expected to meet with no inhabitants but hostile aborigines. These travellers belonged to a whaling station at Portland Bay, which had been established in 1834 by the enterprising Brothers Henty, merchants and bankers of Launceston, Van Diemen's Land. Since that period it has risen into a flourishing government town. Mitchell's further discoveries to the eastward were likewise forestalled by information he received, that a number of settlers from Van Diemen's Land had colonized the shores of Port Phillip during the previous year. On his journey back to Sydney, however, he explored that magnificent territory—the garden of Australia, which he denominated Australia Felix, from its agreeable aspect and fertility. All this extensive country southward from the River Murray to the coast is well watered; and the Snowy Mountains not only temper the climate, but they afford a supply of moisture throughout the summer to the large rivers to which they give birth; while the Great Southern Ocean on three sides throws up clouds of moisture, which descend in abundant rains. Extensive downs occur, which are covered with the best kind of grass, or are gracefully wooded. From Mount Macedon Major Mitchell says he reconnoitred Port Phillip at the distance of 60 miles. "In this region," he adds; "the party crossed ranges of granite, others of trap-rock; the woods forming open forests, which only partially covered the country. This, even in its present state, seems nearly all available for the purposes of agriculture and grazing; and being almost without any aboriginal inhabitants, it is consequently in the best state for the reception of British emigrants."[1] The region described so graphically in this extract is the recently discovered gold region of Victoria; Mount Alexander being the Mount Byng of Mitchell.

Australasia.

Explorations in the interior.

In 1840 Count Strzlecki, an adventurous traveller of great reputation in other lands, and devoted to geological pursuits, made a successful though harassing journey on foot from the Murrumbidgee River southwards through the Australian Alps, and across the Gipps' Land district to Alberton in Corner Inlet; from whence he penetrated through the densest and widest "scrub" or brushwood in Australia, which had hitherto baffled all the settlers and surveyors. His *Physical Description of New South Wales* is at once the most scientific work on Australian geology and mineralogy, and the most practical treatise on Australian agriculture which has hitherto been published.

Strzlecki, 1840.

In 1840 the government of the new colony of South Australia despatched Edward John Eyre from Adelaide, overland to King George's Sound, through the territory denominated Nuyts' Land on the map. He and his party accomplished the journey, after encountering great privations and disasters, some of his party having sunk through sheer fatigue, and their aboriginal guide having been lost. In 1841 he likewise conducted an expedition of discovery towards the interior from Spencer's Gulf. From that point he found a shallow marshy lake, about 20 miles in breadth, extending, in a serpentine form, 400 miles into the interior. This substitute for "the great inland sea," so confidently expected by geographers, he named Lake Torrens. After reaching 29. S. Lat., he returned without crossing the Tropic of Capricorn, the main object of his expedition.

Eyre, 1840-1.

In 1844–5–6 the great purpose of inland exploration, to ascertain the nature of the country in Central Australia, was determined by the "father of Australian discovery," Captain Sturt. From Adelaide he penetrated due north into the very centre of the island; and his account of the desolate stony region he found in the interior, proves beyond a doubt that the vast *terra incognita* of Central Australia is a desert, a second Sahara. He found it depressed in some places below the level of the sea, where, in the rainy season, extensive marshy lakes are formed, which, in the dry season, become parched up, and fringed with incrustations of salt; upon the surface of which vegetation is blasted and animal life is unknown. The sufferings which this undaunted old man encountered uncomplainingly, and the privations which he and his party endured from thirst and hunger under the rays of a sun which frequently raised

Sturt, 1844–5–6.

Australasia.

the temperature to 157°, and the scorching winds of the Austral simoom, are unparalleled, except in the history of the African expeditions of Park and Lander.

Explorations in the interior. Leichhardt, 1843–4–5.

In 1843 an unobtrusive botanist of the name of Dr Ludwig Leichhardt arrived at Sydney from Moreton Bay—where he had been devoting himself to Australian botany and zoology—and solicited the public support to fit out an expedition for the purpose of crossing overland from Moreton Bay to Port Essington. A similar project had, a short time previously, been laid upon the table of the legislative council for the sanction of the governor, by Sir Thomas Mitchell. The legislative body approved of the undertaking, but Sir George Gipps, the governor, referred the matter to the home authorities before he would grant funds for such a purpose. Meanwhile Dr Leichhardt was successful in obtaining for his enterprize public subscriptions of sufficient amount to fit out himself, five Europeans, and an aboriginal native; which ultimately were increased by another volunteer, and a black man, making in all eight individuals; who with a most slender equipment started from the Darling Downs on the 30th September 1844, to prosecute this distant journey through an unknown country for 3000 miles. After hairbreadth escapes from perils "by flood and field," and no less dangerous savages, who killed one of the party, this gallant little band reached their destination on the 17th December 1845, after a journey of fifteen months. The briefest abstract of this indefatigable explorer's additions to Australian geography would extend the present article beyond its limits: they are to be found modestly recorded in his ably written and scientific journal.[1] The volume itself comprises the details of one of the most remarkable enterprizes ever planned by human sagacity and executed by courage and endurance.

In 1846, while the intrepid Leichhardt and his companions had been given up for lost by the people of New South Wales—who were not apprised of his success until his own return by sea on the 29th March of that year—the sanction of the home-government had been obtained to fit out the proposed expedition of Sir Thomas Mitchell, for the same purpose. Sir Thomas altered his plans upon learning the result of Leichhardt's expedition. Keeping to the westward of Leichhardt's route he came upon what appeared to be the source of a large river flowing in a north-westerly direction; which he felt convinced was the upper branch of the Victoria, discovered by Wickham and Stokes, flowing into Cambridge Gulf. After tracing this stream towards Central Australia for about 150 miles, our sanguine explorer left the further prosecution of this enterprize, on his return to Sydney, to his able and accomplished junior on the surveying staff, Edmund B. Kennedy. He shortly afterwards sailed for England, full of the conviction that he had discovered a great highway from Eastern Australia to India by an inland navigable river. Like his predecessor Evans, in his speculations on the course of the Macquarie, he was doomed to be disappointed; for soon after Mr Kennedy found that the supposed Victoria suddenly turned to the southward and became absorbed in the great Australian desert, in the same manner that Oxley found the Macquarie vanish among the marshes.

Kennedy, 1847–8.

In 1847, after Mr Kennedy had returned from his fruitless survey of the Victoria River, the government acquiesced in the suggestions of that gentleman, and other members of the survey department, to prosecute short exploratory journeys into the interior and the northern parts of Australia, as a better method of completing the survey of the country than by long and hazardous expeditions. Mr Kennedy's plan was to survey that part of tropical Australia situated between Cape York in Lat. 10. 43. S., and Rockingham Bay in Lat. 18. 10., a distance by ordinary travelling of not more than 500 miles. But this country, within the influence of the tropical rains, is apparently of such an impassable nature from swamps and prickly scrubs, and so thickly inhabited by hostile aborigines, that this expedition proved to be the most perilous and calamitous of any hitherto attempted in Australia of which we have any record. Out of thirteen persons who started from Rockingham Bay on 5th June 1848, one man alone—Mr Kennedy's aboriginal servant, Jackey Jackey—reached Port Albany, after a six months' journey. At this harbour, a small schooner, the Ariel, commanded by Captain Dobson, was lying at anchor with stores on board, waiting the arrival of the party, to succour them and take them back to Sydney. Here this faithful creature related, in his broken English, his doleful tale. It had taken them a month to extricate themselves from the swamps and thickets of Rockingham Bay. Their sheep and horses could scarcely find any grass to eat. They journeyed along the coast ranges for four months through a frightfully-broken country, almost destitute of game and provender, which reduced both men and horses to the verge of starvation; insomuch that they had to kill twenty-four of the latter to sustain their own lives. Notwithstanding these attempts to support their strength, Mr Kennedy found his men so faint from inanition that he resolved upon leaving eight of them at Weymouth Bay, within about 150 miles of Port Albany, from whence he promised to return for them by sea. Fresh disasters were in the way of this intrepid traveller; one of the men accidentally shot himself, and was disabled. It was agreed that this man and his two mates should remain behind, while Mr Kennedy and his servant were to proceed onwards. Undismayed, he pursued his journey, attended by his faithful servant, and was almost within view of the harbour where he expected succour, when he was inhumanly murdered by a tribe of barbarous savages who speared him to death. The incident of his death, as related in the simple language of Jackey Jackey, is truly affecting. "He then said, 'Jackey, give me paper and I will write;' I gave him paper and pencil and he tried to write, and he then fell back and died. And I caught him as he fell back, and held him, and I then turned round myself and cried; I was crying a good while until I got well; that was about an hour, and then I buried him; I digged up the ground with a tomahawk, and covered him over with logs, grass, and my shirt and trousers; that night I left him near dark."[2] Without delay the vessel was brought round to Weymouth Bay, after a fruitless attempt to find the wounded man and his two companions; who there is little reason to doubt met with the same untimely fate as their leader. Here, alas! two *living skeletons* were all that remained alive of the eight men left at the bay; the other six "withered away, and died from sheer inanition and prostration of the physical energies," as described by one of the survivors, Mr Carron, the botanist to the expedition. His simple and unaffected narrative of their sufferings is the only existing document from which any account of the expedition can be gathered. For although the local government subsequently despatched a party to collect what papers and instruments of Mr Kennedy's might be found in the possession of the natives, scarcely anything of importance was recovered.

Leichhardt, 1848.

The latest, and greatest in contemplation, of these exploring expeditions, the melancholy result of which can scarcely be now a matter of doubt, was that led on by the zealous and indomitable Leichhardt. We have already mentioned his return from his successful expedition to Port Essington in March 1846. Not having then accomplished his original design of penetrating into Central Australia, he rested but a brief space in the settled districts until he was again rally-

Australasia.

Explorations in the interior.

ing a band of adventurers round his Standard of Discovery. "His project was to penetrate to the westward, if practicable, across the great desert, to the settlement of Swan River, a distance little short of 3000 miles in a direct line; hoping to find by the way a succession of oases, like those in the African or Arabian deserts, which would enable him to recruit his party on the journey."[1] After making a false start in 1847, when some of his volunteers, whose enthusiasm quailed before the privations in store for them, abandoned the expedition, he finally left the Darling Downs in the early part of 1848. Since that year no tidings have reached us from the gallant band of explorers, excepting some false rumours of their massacre brought in by the aborigines; which induced the government to despatch a party in July 1852, to make inquiry into the truth or falsehood of the report, but without any satisfactory result. Since the date of his last letter in April 1848, at the furthest white man's home in the interior, from Moreton Bay, five Australian springs have strewed their flowers on the far western shore, but no Leichhardt has revisited these objects of his ardent study: and the probability is, that if he and his companions have not been massacred by savages, their bodies are buried under the sands of the great desert.

It is a remarkable fact, that the most recent of these exploratory expeditions have been the most calamitous, notwithstanding the advantages of former experience, and of modern scientific invention. It is worthy of remark, also, that those unfortunate leaders whose untimely fates have been recorded, were all young men, while the veteran explorers have survived to witness the beneficial results of their discoveries. A new expedition under Captain Stokes has been decided on by the British government. Its chief object will be the exploration of N.W. Australia, for which purpose the expedition is to start from the Victoria River, and to reach the southern extremity of the Gulf of Carpentaria. Captain Stokes hoped to leave England in May 1855.

General view of Australia.

As the structure of the country is brought to light by those discoveries, we observe the broken fragments of its geography gradually pieced together, and at last united into one great whole. Before us on the map we have the grand outline of this island-continent completed, and its limits correctly ascertained; showing a superficies on the earth's surface equal to about three-fourths of the continent of Europe. And although four-fifths of that area is a blank in geography, yet we have sufficient data to determine its principal geographical features. From Wilson Promontory, in 39. 11., the extreme south point, to Cape York in 10. 43. S. Lat., its extreme north, we know that there is a continuous chain of mountains, which, for want of a better name, Sir Roderick Murchison has called the Australian Cordillera,—the backbone of Australia, stretching in one sinuous serrated ridge from S. to N. for 1708 geographical miles, in a straight line, at an average altitude of 1500 feet above the level of the sea; dividing the eastern and western waters of Eastern Australia: and that the water-shed is rapid on its eastern flank, where the sources of the streams are upon an average not more than eighty miles in a direct line from the coast where they disembogue into the South Pacific Ocean; while the western waters have a gradual descent to the great Murray River, flowing through the interior, for an average distance of 500 miles. On the western coast from Cape Leeuwin to N.W. Cape, similar features present themselves in the geographical direction of the rivers and mountain ranges, only on a smaller scale; while between these two mountain parallels exists the Great Australian Desert, a second Sahara; which Sturt has defined on its southern limit, and Mitchell and Kennedy to the eastward. It now remains for future explorers to approach it from the north and from the west to define its general area. At the same time, nothing new of much importance can be contributed to the great geographical problem of what the *terra incognita Australis* is; for we have now sufficient data to solve the question. And it is not unphilosophical to conclude from all that is known of its geography, that the entire island, at some distant geological epoch, formed a vast archipelago, with those two mountain chains forming distinct groups of islands trending north and south, while the desolate region between was the bed of a shallow sea, studded with smaller islands.

Australasia.

General view of Australia.

Of the individuals belonging to the organic kingdoms of nature which inhabit this varied territory, we may observe in this place generally, that they are remarkable for their difference in structure from those of any other part of the world; still the inorganic substances which compose the rocks and minerals are much the same as those found upon other localities of the earth's crust. And although the recent discoveries of her mineral treasures have taken the world by surprise, it is evident that the convulsions of nature which produced these phenomena obeyed the same laws which upheaved the lands of the northern hemisphere. And we shall find, when treating of the gold-discovery, that the light of science in the hands of an eminent geologist guided him to foretell its existence. (For a more detailed view of its surface, geographical divisions, mountains, rivers, lakes, and coasts, see the article AUSTRALIA.)

Aborigines.

The aborigines, wherever they have been met with, are of the very lowest description of human beings. In the journal of the Duyfhen, the N. coast is described as thinly "inhabited by wild, cruel, black savages, by whom some of the crew were murdered;" and the ship Vianen, touching on the western coast about 21° S., observed "a foul and barren shore, green fields, and very wild, black, barbarous inhabitants." In 24° S., Polsert, who commanded the Batavia, saw four natives, whom he describes as "wild, black, and altogether naked, not covering even those parts which almost all savages conceal." Tasman "found in *Hollandia Nova*, in Lat. 17. 12. S., a naked black people, with curly hair, malicious and cruel, using for arms bows and arrows, hazagaeys, and kalawaeys." The S. coast is so barren, and the naked hillocks of sand so continuous, that there appears to be nothing for human inhabitants to subsist upon. "It is not surprising," says D'Entrecasteaux, "that Nuyts has given no details of this barren coast; for its aspect is so uniform, that the most fruitful imagination could find nothing to say of it." None of our navigators, however, saw more than the coast line, which is either of rock or hillocks of sand. But where the country begins to improve towards the eastward, in the neighbourhood of Kangaroo Island, Captain Flinders found not the least vestige of inhabitants; and, from the stupidity of the kangaroos on that island, "which," he observes, "not unfrequently appeared to consider us as seals," he concludes there either were no natives, or that they were ignorant of every kind of embarkation. Towards the northern part of the eastern coast, the same navigator thinks they are somewhat superior to those near Sydney, having belts round the waist, and fillets about the head and upper part of the arm, associating in greater numbers, and dwelling in huts of a superior construction. They also catch fish with nets, which he thinks is alone a feature of distinction from those who only spear the fish, as a net requires more than one person to manage it, consumes much time in making, cannot easily be dragged about, and, in short, must occasion a sense of the advantage to be derived from mutual assistance, and suggest the necessity of a permanent residence.

Notwithstanding these evidences of social progression from the lowest depths of the savage state, and which may be accounted for amongst the tribes inhabiting the great York Peninsula, from their contiguity to the superior races of mankind peopling New Guinea and the Polynesian Islands, the ethnologist can discover clear and distinctive characteristics in the Australian aboriginal people, to warrant him in classifying them as the *furthest removed* type of humanity from any other race with whom we are acquainted. Their general description may be given thus, according to European notions on the standard of humanity, as exemplified in the northern varieties of mankind. They are hideously ugly, with flat noses, having wide nostrils; eyes deeply sunk in the head, large and wide apart, over-shadowed by bushy black eyebrows; the hair black and straight, clotted but not woolly, the males having long curly beards; the mouth is extravagantly wide, with thick prominent lips; and the colour of the skin varies from dark bronze

[1] Mossman and Banister's *Australia Visited and Revisited.*

Australasia.

to jet black. The skull and jaws, when stripped of the hair, integuments, and muscles, present still more distinct characteristics. The cranium is thick and spongy, the inner and outer plates being wide apart, the coronal region flattened. By external admeasurement the capacity of a male skull now in our possession—which was that of a native doctor who died about forty years of age, and furnishes us with a type of these Australian crania *above the average*—is 117 cubic inches; which, when compared with the average size of Anglo-Saxon crania—according to Mr Straton's tables—scarcely equals the admeasurement of a boy ten years of age, laid down by him at 120 cubic inches. The facial angle, according to Count Strzelecki, is between 80° and 85°. The zygomatic process is widely arched; and the lower jaw, although unusually expanded at the base, is short, and forms a remarkably small chin. The molar teeth are flattened more than ordinarily, and sometimes are so smoothly ground by friction in chewing that they frequently resemble the teeth of ruminating animals. Their stature is below the average of the most diminutive European race; and they are wretchedly thin and ill-made, with long lean arms and legs, and short wide feet, the great toe largely developed—which is strengthened to a wonderful degree by use from their youth, in placing that member in the notches they cut with a tomahawk on the trees, when in search of animals for food.

To add to their natural deformity, they thrust a bone through the cartilage of the nose, and stick with gum to their hair, matted with moss, the teeth of men, sharks, or kangaroos, the tails of dogs, jaw-bones of fish, &c., and daub their faces and bodies with red and white clay, and scarify the skin in every part with sharp shells.

On the sea-coast they live principally upon fish, turtle, and shell-fish; the former are caught by nets, hooks, and speared by double and treble pronged spears. In the interior they hunt the kangaroo, wallaby, and emu, with their boomerangs, spears, and waddies; besides which they procure an uncertain supply of opossums, flying squirrels, sloths, storks, cranes, ducks, parrots, cockatoos, eels, lizards, snakes, grubs, ants and their eggs, tuberous roots, wild berries, and honey; in fine, any description of creature or plant from the animal or vegetable world which can supply any nutriment, does not come amiss to the appetites of these attenuated savages. Nay more, although man be described specifically as a "cooking animal," the Australian, in his natural state, scarcely troubles himself with this process, beyond that of throwing a bird or beast on the burning embers of a fire, without skinning it or drawing the entrails; and when it is partially roasted, brushing the singed hair or feathers off, tearing a mouthful or two with his teeth, and throwing it into the fire again to cook another portion of it; when this process of mastication is repeated until the bones are picked.

They have no fixed habitations, the climate generally allowing of their sleeping in the open air, in the crevices of rocks, or under the shelter of the bushes. Their temporary hovels consist of the bark of a tree, or a few bushes interwoven in a semicircular form, tapering at the top, and raised upon a prop-stick, open in front, and forming merely a breakweather, occasionally large enough to shelter six persons from the rain, but most frequently for the accommodation of two. They seem to have no idea of the benefits arising from social life; their largest clans extend not beyond the family circle, of each of which the eldest is called by a name synonymous with that of *father*. They are totally without religion, paying neither the least respect nor adoration to any object or being, real or imaginary. Hence they have nothing to prompt them to a good action, nothing to deter them from a bad one; hence murder is not considered as any heinous crime, and women think nothing of destroying, by compression, the infant in the womb, to avoid the trouble, if brought alive into the world, of carrying it about and finding it subsistence. Should a woman die with an infant at the breast, the living child is inhumanly thrown into the same hole with the mother, and covered with stones, of which the brutal father throws the first. They are savage even in love, the very first act of courtship, on the part of the husband, being that of knocking down his intended bride with a club, and dragging her away from her friends bleeding and senseless, to the woods. The consequence is, that scarcely a female of the age of maturity is to be seen without her head full of scars, the unequivocal marks of her husband's affection.

To these details, generally acknowledged by all travellers, such as Collins, Flinders, Sturt, Mitchell, and others, we shall add some further observations based upon experience and scientific data which have escaped their notice, as illustrative of the ethnographic characteristics of this barbarous people. So various are the languages spoken by the entire radius of tribes located outside the great desert—which, we presume, is untenanted by human beings—that a subdivision of the east and west coasts into lingual districts fifty miles in diameter for 300 miles inland, would give in each district not merely a distinct dialect, but in the majority of cases a different *language* from that of the adjacent tribes. One universal affinity, however, which, we have observed, these languages bear towards each other is, that the letter S is never found in the construction of their words. No evidences of tilling the ground, planting, sowing seed, and reaping the harvest, have been seen by travellers amongst them; which distinguishes them essentially from the Maori race in New Zealand, the races inhabiting the Polynesian Islands to the N.E., and the Malays to the N.W., excepting the tribes located on the extreme north coast. They do not trade or barter with each other or with strangers. Though each family or tribe has a generally recognized boundary within which they hunt and consider their "sit-down" or territory, and beyond which they seldom stray, still they neither exchange, buy, nor sell land among each other; and when their territory was taken possession of by the British, they demanded no equivalent as the New Zealanders have done—they cannot conceive a right of claim to that which is fixed and immovable. Not having any movable property beyond their spears, boomerangs, clubs, shields, opossum-skin rugs, and baskets, their *wealth* is less than that of the industrious bee, and their idea of property inferior to that of the beaver. These rudely-constructed articles of clothing, and weapons of offence and defence, they appear to divide promiscuously among each other, holding possession very much on the old lawless principle that "he may take who hath the will, and he may keep who can." Lunatics or idiots are rarely or never to be found amongst them. Slavery, as understood in the negro sense of the term, does not exist; the married females, however, are to all intents and purposes the slaves of their husbands: virtue and modesty are terms to them, in their purely savage state, utterly unintelligible. Polygamy is recognized and adopted; but from their savage custom of murdering infant female children, the proportion of the sexes is kept nearly equal, and seldom permits of more than one of each cohabiting together. Cannibalism exists among them. The writer has had proofs of several instances; this horrible practice, however, was confined to the bodies of their enemies killed in fight, and of half-caste children of the female sex. They show very little affection for their offspring, especially the males; and we have frequently taxed their philoprogenitive feelings by offering a few pieces of tobacco or a blanket for a child, when we should have easily succeeded in bartering with the fathers, and with no great difficulty overcome the affection of the mothers. Their treatment of the aged is even worse than their neglect of their offspring. These wretched specimens of humanity look at the age of 50 or 60 like octogenarians. Instead of being respected as elders of the tribe, as is the case among other savage races, they are considered as useless members who can no longer fight, hunt, or dig up roots. Hence the garbage of the game captured by the strong son or daughter is thrown with contempt to the father or mother; and they are even prohibited, like the children, from eating the best kinds of food, which the sturdy warriors of the tribe claim as theirs by the law of might. Rheumatism and diseases of the skin are their most prevalent complaints; the result of continual exposure to the weather, and their filthy habits. In every group or tribe of families, there is a doctor-man who uses charms, decoctions of herbs, and personal manipulation to cure the afflicted. In all such services rendered for the general welfare of the whole, or even in any other matter of assistance given to each other, we have never known of any sort of remuneration being tendered, or any special expression of gratitude coming from the patient. That they are capable of being civilized in a measure is shown by the organized troops of black mounted police throughout the south-eastern colonies, and the general employment of them by the colonists as shepherds and mounted herdsmen; nay, so far as intellectual advancement is concerned, in a few instances they have been taught to read and write. But at the best they are uncertain retainers, and cannot be kept to constant labour, while they have a very faint conception of the relations between master and servant. We are confident, also, that the Australian aboriginal would pine and die under any attempts to enslave him by means of the lash and the fetters, which the passive African submits to. Like most other savages, however, they exhibit the extremes of indolence when their appetite is satiated, and of activity when hunger prompts them to hunt for food. Treachery and cunning among them are considered virtues; and it is no disparagement to designate them, morally speaking, a generation of liars. The truth is not in them; in their relations with the Europeans no faith can be placed in what they say, and the local governments take exception to their evidence in a court of justice, or at the utmost value it but slightly.

This unfavourable delineation of the general characteristics of the Australian race, before they have mingled with the European settlers, is one, however, of the faithfulness of which we can confidently challenge disproof. They have, on the other hand, their redeeming qualities. Expert in the capture of game and fish, they will cheerfully share their meals with an unsuccessful neighbour, and will seldom refuse the white man a share—from whom, however, they expect an equivalent. Like children, they are easily pleased, and when

Australasia.

their appetites are satisfied they become a jocular and merry race, full of mimicry and laughter. The sounds of hilarity are often heard ringing joyously through the echoing forests around their camping grounds; and the delight with which they enjoy the pleasures of the dance at their *corrobborees*, is not exceeded by the most enthusiastic frequenters at Almacks. Their conceptions of harmony and melody are very low, and they have no instrument, however rude, to produce musical intonations. Their wild yells of glee, and monotonous *crooning* songs, are reduced to a barbarous kind of measure by striking two pieces of wood together at long and short intervals. As exceptional cases of a better nature (our previous remarks having strictly reference to the Australian aboriginal in his purely savage condition), we can speak of many instances where feelings of great tenderness have been shewn, by the females more especially, and European life and property have been voluntarily rescued from fire and shipwreck. We can likewise testify to the fact of finding faithful and honest followers among them during our travels in the interior. We treated them as *children*, and they were obedient; had we resented supposed injuries they tried to inflict upon us, as if they were responsible *men*, as some have done, we should have exposed ourselves to their deadly enmity. In our transactions with them we dealt on the principle which they themselves considered just. The fidelity and devotion of Jackey Jackey towards the unfortunate explorer Kennedy, are sufficient in themselves to prove that the rudiments of a better nature than they ordinarily display are implanted in their minds.

The history of this race is comprised within a small compass. Records they have none, and their traditions are as evanescent as their dwellings; and like the summer fires, which sweep every vestige of these rude structures from the face of the earth, so their history is buried in oblivion with each succeeding generation. To estimate their present population is likewise a matter of uncertainty. Some years ago the governments instituted a calculation which gave for New South Wales, including Port Phillip, 13,700, and for South Australia, 4500; taking this as a criterion of the other portions of Australia at an approximate census, there would in 1853 be some 210,000 aborigines on the entire island. In this estimate we have allowed for their rapid decrease before the colonizing races of Europe; which may, ere long, render them an extinct people. This subject is fraught with intense interest to the ethnologist. Some morbid philanthropists who have formed associations for the preservation of these races, attribute their extinction to the aggressions by fire and sword upon them by the settlers, and the deadly diseases they introduce. Although to some extent this may be the case, still there is a more powerful influence at work, which ultimately will cause the inferior race to be swallowed up by the superior. Count Strzlecki, states his views in these terms:—"The aboriginal woman, after connection with a European male, loses the power of conception on a renewal of intercourse with the male of her own race, retaining that of only procreating with the white man." From our own investigations, and the testimony of others whom we have consulted, we cannot adduce evidence sufficient to corroborate this statement.[1] The facts are before us that the aboriginal inhabitants of Van Diemen's Land have dwindled down, from between 4000 and 5000, to 8 males and 10 females, who are calculated to die out within 20 years, notwithstanding the efforts of the government to preserve them; whereas, in that time, the same number of our prolific countrymen in the neighbouring isle, would in all likelihood increase tenfold. The tribe also that inhabited the country around Port Jackson and Botany Bay, which Governor Phillip on his arrival found to number about 1500 individuals, is now extinct. The last of its members died in 1849, little more than 60 years after the occupation of their lands by the Anglo-Saxon. These facts are startling, and demand further investigation.

If the rocks and mountains, and the earths, resemble nearly the inorganic substances that are met with in other parts of the world, there is at least a very extraordinary and a distinct characteristic difference in both the animal and vegetable part of the creation, which makes a considerable class of subjects in both these kingdoms peculiar to Australia. The fauna and flora of this arid region are so unique, so far removed in their nature and habits from the generality of species which exist in other parts of the world, so low in the scale of classified animals and plants, and bearing so close an affinity in their structure to the extinct tribes and genera whose fossil remains are found imbedded in European rocks of the eocene geological period, that some ethnologists are tempted to advance the hypothesis that Australia exhibits the most ancient surface-geology for our investigations, of any portion of the terraqueous globe. In other words, that this great south land has existed upheaved from the ocean, contemporary with the bygone epochs of the palæozoic formation, which at a recent geological era was submerged below the sea; and that its groups of living creatures, and its vegetation, have been perpetuated throughout subsequent epochs which have extinguished whole genera of animals and plants in the northern hemisphere. The recent investigations of naturalists in Australia and the surrounding seas, have shown that certain forms of star-fishes and bivalve shells found petrified in the chalk formations of Europe, have existing types in the tropical seas of Australia, and that the Port Jackson shark is the only living example of the ancient group of *Cestrationte* fishes. And while the superficial observer perceives, in the apparently anomalous examples of plants in the grasses and gum-trees,—and animals, in the kangaroo and duck-billed platypus, a mere assemblage of *lusus naturæ*, when compared with the productions of other regions, the attentive student of natural history finds at every step some useful harmony between the individuals of the organic kingdoms, and the peculiar physical geography of this great southern land. Here he finds the grasses containing an unusual pith in their stems, from which they derive nourishment during the dry seasons which occur in this arid climate, when the hollow-stemmed grasses of Europe would perish. And when he examines the structure of that curious animal the duck-billed platypus (*Ornithorhynchus paradoxus*), he discovers that its organism is peculiar to the manner in which it secures food from the water insects, where, in its burrowings in the earth, scarcely any worms are to be found. These and other anomalous forms of the organic world in Australia, are doubtless reconcileable to the universally harmonious system of nature, and require only further investigation to be made manifest.

Australasia.

Animals.

The animals hitherto discovered, with very few exceptions, are of the numerous species of kangaroo or the various opossum type; the former having their hinder legs long out of all proportion when compared with the length of the fore-legs, and both families being *Marsupial*, that is, having a sack under the belly of the female for the reception of the young; of which families, though divided into different genera, there are at least a hundred distinct species. To these marsupial genera may be added another of a singular kind, classed by naturalists under the genus *Ai*, represented by the *wombat* of the natives, or the native bear of the colonists, a herbivorous animal of the sloth kind. Of carnivorous animals, there are very few. The dingo or native dog has some resemblance to the English fox in its appearance and predatory habits, and is the dread of the sheep-farmer. It is supposed, however, not to be indigenous; and with the buffalo, which is found on the northern coast, has no doubt been brought by the Malays, who cross over to fish for trepang, from Java, Timor, and other islands in the Indian Archipelago, as it exhibits very little specific difference from the jackal of these countries. The feline tribe is represented by several species of yellow-spotted cats; and these pretty nearly complete the catalogue of Australian quadrupeds. One animal, however, deserves some specific notice, from the discussions that have arisen regarding the nature and uses of the unusual organic structure of its head: we allude to the duck-billed water-mole of the colonists (*Ornithorhynchus paradoxus*, or *Platypus anatinus*); "a quadruped," says the late Dr White of the British Museum, "with the beak of a bird, which is contrary to known facts and received opinions." The investigations, however, of modern scientific men, have discovered that even this apparent paradox of nature, "setting the bill of a bird upon the head of a quadruped," is in harmony with her laws. This organ, although it has the same function as the bill of a duck, is not, like that appendage, affixed to the skeleton, but merely attached to the skin. It was by Cuvier, along with a somewhat similar Australian animal, the *Echidna*, ranked among the *Edentata*; but now they are both more usually arranged as a distinct class of mammals termed *Monotremata*. They approach the marsupials in possessing the abdominal bones of that order, though they have not the pouch; and they approximate mammals to birds, in possessing a common *cloaca*. The echidna has also a bill-formed mouth, and spines like those of a hedgehog on its body. Australia at the present period is the great metropolis of the order. The flying phalangers (*Phalangista*) are likewise an interesting and

[1] It may be remarked that the assertions of Strzlecki on this subject are more than doubtful, and are at variance with all analogy respecting sexual intercourse between other races of mankind. The same notion once prevailed regarding the negro and white varieties of the human species; but is not founded on fact. The barrenness of the aboriginal females, under such circumstances, will excite little surprise when we consider the well-known effect of promiscuous sexual intercourse in checking fecundity: while the rapid decrease of the Australian native population is further explicable by the frequent practice of infanticide, especially of female children, the excessive labour exacted from their women, the introduction of epidemic disorders by Europeans, and immoderate indulgence in intoxicating liquors.—Ed.

Australasia.

Animals.

beautiful group of marsupials. Crocodiles, turtles, and yangan, or dugong, one of the cetaceæ, inhabit the rivers and harbours of tropical Australia; and in the southern, eastern, and western streams, large fish of the perch tribe abound. The seas swarm with scaled fish and crustacea; many of them edible, others poisonous, and some of the most brilliant colours. Reptiles are frequently met with, but not abundant. There are several species of snakes; some are venomous, but the majority are harmless. Lizards are more plentiful, and all of them harmless; while a large species of iguana affords the natives a delicate kind of food.

The birds are equally singular with the beasts, there being black swans and white eagles; the former everywhere in such multitudes as to spoil a proverb that had held good for two thousand years; and their song as described by Mr Bass, "exactly resembles the creaking of a rusty sign on a windy day." The *Mœnura superba*, with its scalloped tail feathers, is perhaps the most singular and beautiful of that graceful species known by the name of *birds of paradise;* ducks, pigeons, cockatoos, parrots, and parakeets, are innumerable, and of great variety and beauty. The mountain eagle is a magnificent creature, and the emu is, next to the ostrich, the tallest bird that exists, many of them standing full six feet high; and the insect creation presents strange and brilliant forms.

Plants.

The plants are no less singular than the animals. Of these the distinguished botanist Mr Brown has given a very curious and instructive account in his Geographical and Systematical Remarks, in the Appendix to Flinders's *Voyage*. He collected nearly 3900 species of Australasian plants, which, with those brought to England by Sir Joseph Banks and others, supplied him with the materials for a *Flora terræ Australis*, consisting of 4200 species, referable to 120 natural orders; but he remarks that more than half the number of species belong to *eleven* only of those orders. Of the *Eucalyptus* or gum-tree, the largest yet discovered, there are not fewer than 100 different species. "The *Eucalyptus globulus* of Labillardière," says Mr Brown, "and another species, peculiar to the S. of Van Diemen's Land, not unfrequently attain the height of 150 feet, with a girth near the base of from 25 to 40 feet." Of this magnificent genus there are 50 different species within the limits of the colony around Sydney. Of the beautiful and elegant *Melaleuca*, Mr Brown collected upwards of 30 species, all of which, with the exception of the two species *Leucodendron* and *Cajaputi*, appear to be confined to Terra Australis. The tribe of *Stackhouseæ* is entirely peculiar to that country. Of the natural order of *Proteaceæ*, consisting of about 400 known species, more than 200 are natives of New Holland, of which they form one of its characteristic botanical features; the *Banksia*, in particular, being one of the most striking peculiarities of the vegetable kingdom. The *Casuarina*, of which 13 species have been discovered, is another characteristic feature of the woods and thickets of Australia. The most extensive genus, however, is the apetalous *Acacia*, of which there are more than 100 species; and this, with the *Eucalyptus*, "if taken together," says Mr Brown, "and considered with respect to the mass of vegetable matter they contain, calculated from the size as well as from the number of individuals, are perhaps nearly equal to all the other plants of that country." The *Casuarina* and the *Eucalyptus* are represented as furnishing excellent timber for ship-building, and for all the purposes of domestic furniture and agricultural implements; the gum of the *Eucalyptus* is medicinal; and that of one species might be employed as pitch. Freycinet says they procured a resinous substance from the *Xanthorrhea*, which served them to caulk their vessels. The bark of a tree (*Acacia dealbata*) is known to be more efficacious in tanning leather than the oak-bark; and a shrub (*Leptospermum scoparium*) was used by Captain Cook as a substitute for tea. Nutmegs were found by Flinders on the northern coast, but they were small, and had so little of an aromatic flavour, that Mr Brown gave the plant the specific name of *insipida*. Among the curious productions of the vegetable world is the *Nepenthes distillatoria*, or pitcher plant, of which a very correct and detailed drawing is given in the Atlas to Flinders's *Voyage*. The pines of the genus *Auracaria* have the double-dotted vascular tissue of the carboniferous *Coniferæ*. The *Eucalypti* or gum-trees shed their bark annually instead of their leaves; while the latter hang vertically from the branches, instead of horizontally, as in most English forest-trees; and the *Casuarinæ* or she-oak trees have the jointed articulations of *Hippuris* instead of leaves. Altogether, the anomalous characters of Australian botany, though presenting organic phenomena distinct from those of the northern hemisphere, are in harmony with the branches of the animal kingdom already alluded to. Since Brown's *Prodromus* was published in 1810, very little has been added to that profound work. And it is a remarkable fact, that few genera, if any, have been discovered since that eminent botanist and his patron Sir Joseph Banks first collected the plants of Botany Bay. Although Cunningham, Labillardière, and others, have added materially to the list of species, there is still a vast region open to botanic enterprize, especially in the unexplored mountain ranges of the great Australian Cordillera.

Australasia.

General view of Van Diemen's Land.

II. Having marked the progressive discovery of this fair and fertile island, until it was ascertained to be such by Tasman, Marion, Furneaux, Cook, D'Entrecasteaux, Bass, and Flinders, we shall not think it necessary to notice the minor discoveries of Bligh, Hunter, Cox, &c., but proceed to give a general account of its dimensions, surface, and natural productions. It is situated between the parallels of 41. 0. and 43. 32. S. Lat., and 144. 32. and 148. 25. E. Long.; its medial length from N. to S. being about 160, and breadth from E. to W. 145 geographical miles. Its surface possesses every variety of mountain, hill, and dale,—of forests and open meadows,—of inland lakes, rivers, and inlets of the sea, forming safe and commodious harbours,—that can render a country valuable or agreeable; and it enjoys a temperate climate, which is perhaps not very different from that of England, though less subject to violent changes. In May, corresponding to our November, Labillardière observed the mountains in the interior covered with snow. The western and southern coasts are bold, steep, and rocky; the latter terminating so abruptly as to appear as if it had been broken off, and the group of islands named De Witt's Isles, to the southward, twelve in number, formed out of the fragments. Cook found the cliffs on the eastern side composed of sandstone; but the vast buttresses that look towards the southern seas of ice are stated by Flinders to be composed of basaltic columns, appearing like so many stacks of chimneys. Labillardière found, near this southern extremity, a stratum of coal $3\frac{1}{2}$ feet thick and 200 fathoms long, resting on sandstone.

The soil, in general, is represented as more productive than that of the E. side of Australia; and the island has the advantage of being intersected by two fine rivers, rising near the centre; the one named the Tamar, falling into Bass's Strait on the N., and forming Port Dalrymple; the other, the Derwent, which discharges itself into the sea on the S.E. extremity, spreading its waters, in the first instance, over the Great Storm Bay, which communicates with North Bay, Norfolk Bay, and Double Bay, on the E., and with D'Entrecasteaux's Channel on the W. The Tamar in its course receives three streams—the North Esk, the South Esk, and the Lake River; and the tide flows about 30 miles up the river, to the point where it is joined by the two Esks. At this spot is situated the flourishing town of Launceston; having a population of about 6500. At the head of the western arm of Port Dalrymple is situated George Town, on the skirt of a beautiful, rich, and well-wooded country. There is also a town named Hobart Town, which is now the capital, on the right bank of the Derwent, about five miles inland, with a population, in 1851, of 14,000 inhabitants. The country between these two towns is everywhere rich and beautiful, abounding in grassy plains, marshes, and lakes, bounded on each side by hills, well clothed with wood, rising into high and rocky mountains. A turnpike road now bisects the island between Launceston and Hobart Town,—a distance of 130 miles, which is accomplished by stage-coaches within 12 hours.

The description given by D'Entrecasteaux of the channel that bears his name, and the surrounding shores, corresponds generally with the following animated account of it from M. Péron, ten years afterwards. "Crowded on the surface of the soil are seen on every side those beautiful *Mimosas*, those superb *Metrosideros*, those *Correas*, unknown till of late to our country, but now become the pride of our shrubberies. From the shores of the ocean to the summits of the highest mountains may be observed the mighty *Eucalyptus*, those giant trees of Australasian forests, many of which measure from 162 to 180 feet in height, and from 25 to 30 and even 36 feet in circumference. *Banksia* of different species, the *Protea*, the *Embothria*, the *Leptosperma*, form an enchanting belt round the skirts of the forests. Here the *Casuarina* exhibits its beautiful form; there the elegant *Exocarpus* throws into a hundred different places its negligent branches. Everywhere spring up the most delightful

Australasia.

thickets of *Melaleuca, Thesium, Conchyum, Evodia,* all equally interesting, either from their graceful shape, the lovely verdure of their foliage, the singularity of their corollas, or the form of their seed-vessels."—*Voy. aux Terres Australes.*

All the navigators who have visited the southern part of Van Diemen's Land describe the natives as a mild, affable, good-humoured, and inoffensive people; with the exception of Marion, the effect of whose fire-arms, Labillardière thinks, had made them afraid of Europeans. Subsequently the settlers found them a hostile and treacherous race, probably from the same cause. Flinders and Bass conceived that the natives of this island were sunk still lower in the scale of human existence than those in the neighbourhood of Port Jackson, though they saw but one man, and he is described as having "a countenance more expressive of benignity and intelligence than of that ferocity or stupidity which generally characterized the other natives." They are obviously the same people as those of Australia. The women refused from Cook's people all presents, and rejected all their addresses, not so much from a sense of virtue, it was supposed, as from the fear of the men, of whom they stood in great awe. With the convicts and free settlers they had free intercourse. In some places were found miserable huts of twigs, and rude baskets made of a juncus or rush; but these were all the signs that appeared of civilization. Cook, D'Entrecasteaux, and Baudin, all observed many of the largest trees with trunks hollowed out, apparently by means of fire; and as the hollow side invariably faced the E. and S.E., the lee-side to the prevailing winds, it was concluded they were intended as habitations. In D'Entrecasteaux's Channel only were indications of huts made of the bark of the *Eucalyptus*, consisting of three rolls stitched together. Of the numerous tribes who peopled this island when it was first colonized by the British, only 18 men and women now remain. At the early settlement it was a penal colony, and the natives were considerably thinned by a war of extermination carried on by the convicts and settlers against them, which ended in their being conveyed to Flinders' Island in Bass's Strait, from whence the miserable remnant now at Brown's River, near Hobart Town, were brought to end their days in peace.—D'Entrecasteaux, Labillardière, Flinders, &c.

New Guinea or Papua.

III. New Guinea, or Papua, is, after Australia, not only the first in point of magnitude, but claims a priority in discovery over that and every other island in the Australasian Sea. In the year 1526, when the Portuguese and the Spaniards were disputing their respective claims to the Spice Islands, Don Torge de Meneses, of the former nation, had, in his passage from Malacca to the Moluccas, by extraordinary and accidental circumstances, discovered the N. coast of Papua, so called, according to some, because the word signifies *black*, which was the colour of the natives, or *curled hair*, according to others. Meneses remained at a port called Versija till the change of the monsoon, and then returned to the Moluccas. The next navigator who touched at Papua was Alvarez de Saavedra, on his homeward voyage from the Moluccas in 1528, for New Spain; and from an idea that the country abounded in gold, he gave it the name of *Isla del Oro*. He staid a month, and obtained provisions; but some Portuguese deserted with the only boat the ship had, and were left behind. They found their way, however, to Gilolo, and reported that Saavedra had been wrecked; but on his subsequent arrival they were tried, condemned, and executed. He is supposed to have added about 50 leagues of discovery to that of Meneses. In 1529 Saavedra sailed a second time from New Spain, and, according to Galvaom (or Galvano), followed the coast of Papua eastwards above 500 leagues.

In 1537 Gonzalvo and Alvarado were despatched on discovery by the viceroy of Peru; but the former being killed in a mutiny, the crew chose another commander; and the first land they made was Papua. The ship was in so crazy a state that she was abandoned; the crew, only seven in number (the rest having died of hunger and fatigue), were made captives, and carried to an island called *Crespos* (curly-haired men), whence they were sent to the Moluccas and ransomed.

In 1545 Ynigo Ortiz de Retz, in his voyage from Tidore to New Spain, came to an archipelago of islands near the land of Papua; sailed 230 leagues along the N. coast; and not knowing it had been before visited by Europeans, he called it *Nueva Guinea*, from the resemblance of the natives to those of the coast of Guinea.

Australasia.

In 1606 Torres made the E. coast of New Guinea, in his way to the Moluccas, sailed westward 300 leagues, doubled the S.E. point, sailed along the southern coast, saw the northern coast of New Holland, and passed the strait which now bears his name. He describes the coast of New Guinea as inhabited by a dark people, naked, except a covering round the middle, of painted cloth made of the bark of a tree. They had arms of clubs and darts ornamented with feathers. He fell in with many large islands, ports, and rivers. Towards the northern extremity he met with Mahometans, who had swords and fire-arms.

In 1616 Schouten came in sight of a burning mountain on the coast of New Guinea, which he named Vulcan, and immediately after of the coast itself. The island was well inhabited, and abounded with cocoa-nuts; but no anchoring ground could be found. The natives were black, with short hair; but others appeared of a more tawny colour, with canoes of a different shape. Among the islands in sight to the northward, four small ones continually smoked. On approaching the main land, the natives, whom he calls real Papoos, came off, "a wild, strange, and ridiculous people, active as monkeys, having black curled hair, rings in their ears and noses, and necklaces of hogs' tusks." They had all some personal defect; one was blind, another had a great leg, a third a swelled arm; from which Schouten concluded that this part of the country was unhealthy, an inference which was confirmed by observing their houses built upon stakes eight or nine feet from the ground. At the two little islands of Moa and Insou, on the N.E. coast, the friendly natives supplied them with abundance of cocoa-nuts. At 28 leagues from Moa, Schouten fell in with a group of 14 small islands covered with wood, and apparently uninhabited; but sailing to the northward, they were followed by six large canoes, the people in which were armed with javelins. Those in some canoes from another island were of a tawny complexion, had long curly hair, and appeared by their persons and language to be a different race from the natives of Papua: they had rings of coloured glass, yellow beads, and vessels of porcelain, which were regarded as "evidences of their having communication with the East Indies." Schouten's Island is the largest of this group. Tasman visited all these islands and the coast of New Guinea in 1643, but made no discoveries in this part of his voyage.

Our countryman Dampier saw the coast in 1699, but did not land: the natives came off to his ship, and he speaks in admiration of their large and picturesque *proas*. He discovered, however, a strait unknown before, which divides New Guinea from New Britain, and is now called after his name. Bougainville was less fortunate, when, in 1768, he touched on the coast of what he considered a separate island, and to which he gave the name of Louisiade. D'Entrecasteaux, in 1792, passed along the northern coast of Louisiade, and through Dampier's Strait, but left the point of its identity with or separation from New Guinea undecided.

Sonnerat published *A Voyage to New Guinea*, though he evidently never was there, but describes the natives and productions from what he saw and from what he could collect at the island of Gibby, to the eastward of Gilolo.

Forrest, in 1775, anchored in the Bay of Dory, on the northern extremity of New Guinea, and collected some information respecting the inhabitants from a Mahometan Hadji, who accompanied him. Captain Cook, also, in his first voyage in 1770, made the coast in about 6. 30. S. Lat., a little to the northward of Cape Valscher, but did not bring his ship to anchor, on account of the hostility of the natives. A party landed near a grove of cocoa-nut trees, and not far from it found plantain and the bread-fruit tree. The breeze from the trees and shrubs is said to have been charged with a fragrance not unlike that of gum *benjamin*.

Australasia.

Three Indians rushed out of the wood with a hideous shout, and ran towards the party; the foremost throwing something out of his hand which burnt like gunpowder, the other two hurling their lances at the same time. Before they reached the pinnace, from 60 to 100 had collected, all stark naked; their appearance as to stature, colour, and crisped hair, resembling that of the New Hollanders. They let off fires by four or five at a time, but for what purpose could not be imagined. These fires appeared to be discharged from a piece of stick, probably a hollow cane; and the fire and smoke exactly resembled those of a musket, but without any report. Those who were on board ship, at a distance, concluded they had fire-arms; and even those in the boat might have supposed them firing volleys, had they not been so near as to ascertain that there was no report. Torres had observed something of the same kind in about 4. S. Lat. on the same coast, where, he says, the inhabitants were black, but better clothed than those southward; that among the weapons used by them were hollow bamboo sticks, which they filled with lime, and by throwing it out endeavoured to blind their enemies. This explanation, however, does not account for the *fire*. Forrest says that the Chinese from Tidore trade with Papua under Dutch colours; perhaps, therefore, gunpowder may be one of the articles carried by them in exchange for the slaves, ambergris, sea-slugs (*Sipunculus edulis*), tortoise-shell, lories, birds of paradise, &c., which they carry back to China.

The S.E. coast of New Guinea was visited in June 1793 by Mr Bampton, master of the Hormuzeer, and Mr Alt, master of the Chesterfield, two British merchant vessels, who, in their endeavours to find a passage to the N.W. while beating up the Great Bight of this island, added some valuable information to what was previously known of that part of the coast. Captain Bristow, also the discoverer of the Auckland Islands, visited in 1806 the northern shores of the smaller islands, which were described by D'Entrecasteaux in 1793. But the southern shores of the Louisiade remained unexplored from the period of Bougainville's voyage in 1768 until the year 1840, when a French navigator, Captain D'Urville, attempted a flying-survey of them in the Astrolabe during his voyage round the world. He was not sure, however, whether the land he observed belonged to New Guinea or the Louisiade, although he passed a multitude of islands with navigable channels between them.

In 1845 Captain Blackwood, in H.M.S. Fly, surveyed 140 miles of the S.E. coast of New Guinea within the Great Bight. Here he found a low muddy shore extending many miles inland of the same character, intersected by channels, which evidently are the estuaries of streams. One of these he ascended for a distance of 20 miles in the ship's boats, and saw numerous native villages built at intervals along the banks; but being confronted by the inhabitants, who appeared to be of warlike disposition, he considered it dangerous to attempt a landing. This partial survey was followed up in 1846 by Lieutenant Yule in H.M. schooner Bramble, who laid down the coast-line from where Blackwood's survey had terminated E. of Aird's River, along the S.E. shore of the bight. As he proceeded southerly, where the coast trends to the eastward, he found the country inland gradually improve in aspect from low mud banks to densely wooded hills; with a lofty range of mountains in the distance. At this point where he sighted a high peak of this mountain-chain—which now bears his name—he returned to Australia to await further orders.

On the 10th of June 1848, Captain Owen Stanley in H.M.S. Rattlesnake, accompanied by the Bramble, Lieutenant Yule, as tender, commenced a further survey of the doubtful S.E. peninsula of New Guinea, and Bougainville's Louisiade. During their combined indefatigable exertions for four months, they not only determined the fact that the latter island is separated from the mainland, but that it forms one of several groups of smaller islands, more or less surrounded by dangerous coral reefs, which extend for upwards of 200 miles E. by S. of the great Papuan Island, between 151. and 154. 30. E. Long., and the parallels of 11. and 12. S. Lat.: the entire assemblage of island and reefs, including the Calvados Group, being now denominated the Louisiade Archipelago.

Australasia.

Much valuable information has been added to the natural history and ethnography of those coral-bound isles which Captain Stanley has now determined upon the charts of Australasia, by Mr John Macgillivray, the naturalist who accompanied the expedition; and who has furnished us with the journal of the voyage, which the death of the captain prevented himself from publishing. In his graphic descriptions of these new and interesting islands, he thus describes their appearance: "From the anchorage we enjoyed an extensive view of the south-eastern portion of the Louisiade Archipelago. On the extreme right is the large S.E. island, with its sharp undulating outline, and Mount Rattlesnake clearly visible, although distant 45 miles. Next, after a gap partially filled up by Pig Island, Joannet Island succeeds, 10½ miles in length, not so high as South-east Island, but resembling it in dimness of outline: its highest point, Mount Asp, is 1104 feet in height. Next come the Calvados, of various aspect and size, some with the undulating outline of the larger islands, others rising more or less abruptly to the height of from four to upwards of nine hundred feet. They constitute a numerous group—upwards of 40—some of which, however, are mere rocks: they are delineated upon the Rattlesnake's chart, and there are others to the northward. Behind them, in two of the intervals, the large and distant island of St Aignan (so named after one of D'Entrecasteaux's lieutenants) fills up the background, falling low at its eastern extreme, but the western half is high and mountainous, with an elevation of 3279 feet. Further to the westward, the last of the Calvados in this view was seen to form a remarkable peak, 518 feet in height, to which the name of Eddystone was applied; and still further to the left, Ile Real of D'Urville's chart shoots up to the height of 554 feet, as a solitary rocky island with a rugged outline and an abruptly peaked summit."[1]

Leaving these islands, Captain Stanley proceeded on his general survey along the S.E. coast of New Guinea, until he reached that point of land where Lieutenant Yule in the Bramble had left off. On making the S.E. cape of the island, the land appeared of a mountainous character inland; and this continued increasing in elevation for 250 miles, until he came to Yule's Peak. It is evident that this great mountain-chain divided the watershed on each side of the peninsula. On determining the altitude of this range of mountains, it was found to average double that of the Australian Alps—the highest section of the great Cordillera of that island. Mount Owen Stanley is 13,205 feet in height, being more than double that of Mount Kosciusko (6510 feet)—the highest mountain in Australia. Of fifteen other peaks in the range, whose altitudes are laid down on the Rattlesnake's chart, eight are above 7000 feet. Doubtless there are rich fields for discovery to future naturalists on these tropical-alpine ranges. At present, however, the hostile disposition of its savage occupants renders it inaccessible to European explorers.

General view of Guinea.

If we except the Louisiade Archipelago, New Guinea extends in a S.E. by E. direction from the Cape of Good Hope, nearly under the equator, to South-east Cape, in 10. 35. S., being in length about 1200, and medial breadth about 150 geographical miles. The accounts of all the navigators who have touched on the different parts of its coast, describe it as a rich and magnificent country, containing, in all human probability, from its situation and appearance, the most valuable vegetable products of the Moluccas and the several Asiatic islands. Forrest found the nutmeg-tree on Manaswary Island, in the Bay of Dory; and he learned that a people in the interior, called

[1] *Voyage of H.M.S. Rattlesnake, Captain Owen Stanley.* By J. Macgillivray, vol. i. p. 241.

Australasia.

Haraforas, cultivate the ground, and bring their produce down to the sea-coast; that they are very poor, and some of them have long hair; and that they live in trees, which they ascend by cutting notches in them. The people of New Guinea, in many parts of the coast, live in huts or cabins placed on stages which are erected on posts, commonly in the water, and probably as a protection against snakes and other venomous creatures, though Forrest seems to think against the Haraforas. On these stages they haul up their proas or canoes. These people are invariably described as being hideously ugly. Their large eyes, flat noses, thick lips, woolly hair, and black shining skin, impressed the early navigators with the idea that they were of African origin; but closer investigation of late years has shown them to be a very mixed race indeed. Mr Macgillivray resolves them into several indistinct types with intermediate gradations. Thus, occasionally he met with strongly marked negro characteristics, but still more frequently with the Jewish cast of features; while every now and then a face presented itself which struck him as Malayan. Although the hair of these aborigines was invariably frizzled out into a mop, and woolly, instances were met with in both sexes where it was black, soft, and curly, while in others it was red and frizzly, and the males mostly beardless. The colour of the skin varies from a light to a dark copper shade; and their stature does not average more than 5 feet 4 inches. Instead, therefore, of considering them a pure race, these late investigations would lead us to suppose that the races from all the neighbouring Polynesian and Malayan islands had their representatives on this beautiful and fertile group of islands; who have amalgamated and formed the most warlike race in the Australasian seas. Their habits, however, are much the same as their neighbours; and they show equal skill in the management of their canoes and weapons, and in the building of huts. The Papuans also increase their natural deformity by passing bones or pieces of stick through the cartilage of the nose, and as already mentioned, frizzing out their curly locks like a mop, sometimes to the enormous circumference of 3 feet. They appear, however, to be one degree farther removed from savage life than the Australian aborigines, having permanent houses, and both men and women wearing wrappers round the waist, which are among the articles brought to them by the Chinese and Malays.

Animals.

The only quadrupeds known to exist on this island are dogs, rats, and wild hogs; but the feathered race are of great beauty and infinite variety. New Guinea is the native country of the bird of paradise. They are said to migrate in large flocks, in the dry monsoon, to the islands of Arroo, and other islands to the W. and N.W. of New Guinea. The great crown pigeon, parrots, lories, and minas, are natives of Papua.

The whole of this great country is indented with deep bays on every side, some of which nearly intersect the island; and the coast is surrounded on every side by a multitude of small islands, all peopled with the same description of blacks, excepting those already mentioned on the N.W., near the equator, most of which are under the government of Mahometan Malays, with whom both the Dutch and Chinese have long kept up intercourse.

New Britain, New Ireland, and neighbouring islands.

IV. There can be little doubt that this extensive range of islands was partially seen by Le Maire and Schouten in 1616, who, after discovering the Groene Island and the Marquen Islands, steered along the northern coast of New Ireland, as did Tasman also in 1642. Dampier, however, first ascertained New Britain to be an island distinct from New Guinea, by passing the strait which has since borne his name. He visited Port Montague on this island, and speaks of the black natives resembling the Papuans, their dexterity in managing their canoes, their woody hills, fertile

Discovery.

vales, and delightful rivulets. He also anchored in Slinger's Bay, on New Ireland, which he conceived to be the same land with New Britain; but Carteret, in 1727, discovered and passed through a strait which separates them, and to which he gave the name of St George's Channel. The Admiralty Islands of Carteret, to the north-westward of New Britain, had previously been discovered by Schouten, and named the Twenty-five Islands. New Britain was seen by Roggewein in 1722, and by Bougainville in 1768.

D'Entrecasteaux, we believe, was the last navigator who passed along the N. coast of New Britain, and through St George's Channel, which divides it from New Ireland, and from thence to the Admiralty Islands; and from his voyage, published by Rossel, together with Labillardière's and Carteret's, we shall extract a few gleanings.

General description.

The extent of New Britain and Ireland is not exactly known, nor have they been sufficiently explored to enable geographers to lay them down with accuracy, or even to state what number of islands the group consists of. One of considerable extent lies off the N.W. end of New Ireland, which has been named New Hanover, and is itself surrounded by low woody islands. The whole group occupies a space between 2. 30. and 6. of S. Lat., and 149. and 153. of E. Long., and may probably contain an area not less than 10,000 geographical square miles.

Australasia.

Natives.

Carteret, in passing through the strait, saw but few natives on the S. coast of New Ireland. These showed marked signs of hostility, and were armed with lances headed with flint; they had also slings and good fishing-tackle. They were black, and had woolly hair, but their lips, he says, were not thick, nor their noses flat; their cheeks were streaked with white, and their hair and beards were covered with a white powder. Their canoes were long and narrow, and had generally outriggers; one of them measured 90 feet in length, and was formed out of a single tree. The two large islands, and the whole group, in fact, were nearly covered with wood; and thick cocoa-nut groves skirted all the low parts of the coast. Labillardière says that New Ireland produces nutmegs; and he also mentions a new species of the Areca palm, 108 feet high, the stem consisting of hard solid timber.

The natives of the Admiralty Islands, lying to the N.W., were found by Carteret to be less black than those of New Britain and Ireland, with agreeable countenances, not unlike Europeans; their hair was curly, smeared with oil and red ochre, and their bodies and faces painted with the same material; the glans penis was covered with the shell called the *bulla ovum*, serving the same purpose as the wooden sheath of the Caffres in South Africa, whom, indeed, they seem to resemble as closely as the natives of New Guinea do those of the western coast of Africa. The women wear a bandage round the waist. The central island is tolerably large, and of a beautiful appearance, clothed with the most luxuriant verdure, and cultivated to the very summit. Among the groves of cocoa-nut trees are numerous habitations, and the natives have evidently attained to a higher degree of civilization than their southern neighbours: they use earthen vessels, and chew the betel leaf with chunam or lime. This central island is surrounded by nearly 30 small flat islets of coral, and reefs in the various stages of progress towards islets.

Proceeding to the westward and to the north-west, we meet with other little clusters of islands, as the Hermites, the Portland, the Echiquier (chess-board), vulgarly called Exchequer Islands, all of which consist, like the Admiralty Archipelago, of a larger central island surrounded by a chain of islets and reefs, most of them covered with beautiful verdure. The natives of these groups, as they approach the equator, gradually assume a lighter colour and longer hair, till they lose entirely the negro character, and merge into that of Malays and other Asiatic islanders.—See Schouten, Dampier, Carteret, Labillardière, &c.

Solomon's Islands.

V. This archipelago of islands was one of the first discoveries of the Spaniards in Australasia, though the credit of it is given to Alonzo de Mendana, who was sent on an expedition of discovery in 1567 from Callao by the viceroy of Peru. He anchored in a port on the island of Santa Ysabel, to which he gave the name of Porta de la Estrella; and he also built a brigantine to make further discoveries, in which she was particularly successful, having fallen in with no fewer than thirty-three islands, "of very fine prospect." Many of them were of considerable size, to which they gave particular names, as Galera, Buonavista, Florida, San German, Guadalcanar, San Christoval, Santa Catarina, and Santa Ana. Guadalcanar, however, was the most attractive, having a port which they named De la Cruz, and a river which they called Galego. Of this island Mendana took possession for the king of Spain. When the voyage was published, the name of Solomon's Islands was given to the group, "to the end that the Spaniards, supposing them to be those isles from whence Solomon fetched gold to adorn the temple at Jerusalem, might be the more desirous to go and inhabit the same;" but it has been said that Mendana's advice was, that they should not be colonized, "that the English, or others, who pass the Strait of Magelhanes to go to the Moluccas, might have no succour there, but such as they get from the Indians." The truth, however, is, that Mendana, on a second voyage for the discovery of the Solomon Islands, returned without being able to find them, which

Australasia.

gave occasion to the remark, that "what Mendana discovered in his first voyage he lost in his second." He discovered, however, in this second voyage, the great island of Santa Cruz, which is situated at the S.E. extremity of Solomon's Islands, and may very fairly be considered as one of the group. This island, which has an excellent harbour, La Graciosa, was first revisited after Mendana's discovery by Carteret, in 1767, who changed its name to that of Egmont, and made it the principal island of a group which he called Queen Charlotte's Islands. Here Mendana died, and Quiros succeeded to the command; but the search for Solomon's Islands was abandoned when they were not more than 40 leagues from Christoval. It is a singular fact that Solomon's Islands, whose name was sufficient to tempt adventurers, were lost to Europeans for two centuries after their discovery, and that we know at present little, if any, more than Mendana gave to the world after his first voyage. They were revisited by Bougainville in 1768; by M. Surville in 1769, who, from a ridiculous mistake, called them the Archipelago of the Arsacides, to mark the natives as assassins; by Lieutenant Shortland of the British navy, in 1788, who chose to call them New Georgia; and frequently, since that time, by various British and French navigators.

Natives.

Santa Ysabel, says Mendana, was inhabited by people who had the complexion of mulattoes, with curly hair, and little covering to their bodies; who worshipped serpents, toads, and such like creatures; whose food was cocoa-nuts and roots; and who, it was believed, ate human flesh, "for the chief sent to the general a present of a quarter of a boy, with the hand and arm." Buonavista is twelve leagues in extent, very fertile, and well peopled, the natives living in regular villages or towns. On Florida, twenty-five leagues in circuit, the natives dyed their hair red, collected together at the sound of the conch-shells, and ate human flesh. Sesarga was well inhabited, produced plenty of yams and bread-fruit, and here the Spaniards saw hogs. In the midst of the island was a volcano continually emitting smoke. They saw bats which measured five feet between the tips of the wings. At Gaudalcanar they received in barter two hens and a cock, the first fowls that had been seen. At San Christoval the natives were very numerous, and drew up to give battle to the Spaniards, their arms being darts, clubs, bows and arrows; but they were dispersed by the fire of the muskets, which killed one Indian, and wounded others. In the neighbouring village was found a quantity of cocoa-nuts and almonds, sufficient to have loaded a ship. Santa Ana was well peopled and fertile. It has a good port on the E. side, where the Spaniards were attacked by the natives, who wounded three of the invaders, while a dart pierced through the target and arm of the Spanish commanding officer. The blacks had boughs on their heads, and bands round their waists. The Spaniards observed here hogs and fowls.

New Hebrides.

VI. To the S.E. of Solomon's Islands, and between the parallels of 14. 30. and 20. S. Lat., are found a number of islands, some of very considerable magnitude, called the New Hebrides or Hebudes. They were first discovered in 1606 by Pedro Fernandez de Quiros, who, with Luis Vaez de Torres, was sent by the king of Spain from Lima with two ships and a zabra (launch) to establish a settlement at the island of Santa Cruz, and from thence to go in quest of the Tierra Austral or southern continent. This voyage has been considered, and justly so, among the most celebrated undertaken by the Spaniards since the time of Magelhanes. In April 1606 they discovered an island, to which they gave the name of Santa Maria, from whence they saw another island to the southward, "so large," says Torres, "that we sailed for it." On the 2d May they anchored in a bay large enough to hold a thousand ships, to which they gave the appropriate name of San Felipe y Santiago. Quiros at once determined that he had now discovered the long-sought-for southern continent, and in this conviction named it the Australia del Espiritu Santo. Two rivers fell into the bay, one the Jordan, the other the Salvador. The surrounding country was beautiful, and is thus described by the historian of the voyage: "The banks of the rivers were covered with odoriferous flowers and plants, particularly orange flowers and sweet basil, the perfumes of which were wafted to the ships by the morning and evening breezes; and at the early dawn was heard, from the neighbouring woods, the mixed melody of many different kinds of birds, some in appearance like nightingales, blackbirds, larks, and goldfinches. All the parts of the country in front of the sea were beautifully varied with fertile valleys, plains, winding rivers, and groves, which extend to the sides of the green mountains."—Torquemada, as quoted in Burney's *Account of Discoveries in the South Sea.*

Australasia.

Of this terrestrial paradise, which the Spaniards regarded as their own, it was intended to take immediate possession. They landed in great numbers; the islanders also were numerous, but became alarmed, made them presents, and signified a wish for them to return to their ships. They landed, however, from their boats, upon which the chief drew a line on the ground with the end of his bow, and made signs that the Spaniards must not pass that boundary. It is said that Torres, to show his contempt of the idea of being restrained by barbarians, immediately passed the line. A battle ensued, in which the chief was killed, and all the rest fled into the woods. This rash act, however, was fatal to the views of the Spaniards, who never afterwards could prevail on the islanders to have any friendly communication with them; and they left this country, after some ridiculous formalities of taking possession in the name of Philip III., and founding a city, dignified with the name of the *New Jerusalem.*

So anxious was Quiros of "adding the Australia del Espiritu Santo to the other possessions of the Spanish monarchy," that, after his return to Spain, he is said to have presented no less than fifty memorials to the king. One of these, which was printed at Seville, begins thus: "I, Captain Pedro Fernandez de Quiros, say, that with this I have presented to your majesty eight memorials relative to the settlement which ought to be made in *Australia Incognita.*" In these memorials he enumerates the many valuable productions of this supposed southern continent,—cocoa-nuts, plantains, sugar-canes, yams, batatas, oranges, limes, papas, pumpkins, almonds, nutmegs, mace, ginger, pepper in great quantities, and woods for "building any number of ships." The animals are hogs, goats, and dogs; fowls, and a variety of useful birds; various good fish, and pearl oysters. The climate is described as so fine, with such a freshness in the air, that neither by labour, exposure to the sun, or rain, or dews, nor by intemperance, did any of the Spaniards fall sick; and among the natives many aged people were seen. They wear a covering round the middle: Torres says they are all black and naked. They are described by Quiros as corpulent and strong, cleanly, cheerful, sensible, and grateful: their houses, built of wood and thatched, stood, not on posts, but on the ground. They weave nets, and make earthen vessels, have plantations inclosed with palisades, construct vessels which navigate to distant countries, and have places appropriated for burying the dead; and, he adds, as the last and decisive test of their progress in civilization, "they cut their hogs and make capons."

Description. Natives.

This archipelago of islands, like that of Solomon, was lost to the world for a century and a half, when Bougainville revisited them in 1768. Except landing on the Isle of Lepers, however, he did nothing more than discover that the land was not connected, but composed of islands, which he called the *Great Cyclades;* which, on being more accurately and extensively explored by Cook in 1774, underwent another change to that of New Hebrides, which they now bear in all our charts. According to the survey of our great navigator, they consist of Tierra del Espiritu Santo, the largest of the whole, St Bartholomew, Mallicolo, the Isle of Lepers, Aurora, Whitsuntide, Ambrym, Apee, Paoom, Three-hills, Sandwich, Montagu, Hinchinbrook, Shepherd's Isles, Erromango, Tanna, Immer, Annatom, and Erronan. The two which are more particularly described are Mallicolo and Tanna, the natives of which differ remarkably in their persons and language; those of the latter having curly but long hair, dark but not black, and without anything of the negro character in their features, which are regular and agreeable, their persons slender, active, and nimble. They were found to be

Australasia. hospitable, civil, and good-natured; but they displayed a jealousy of their visitors seeing the interior of the island, which could only be equalled in Japan or China. All the plantations were fenced, and laid out in a line; they consisted of sugar-canes, yams, plantains, bread-fruit, &c. The yams were remarkably fine, one of them weighing 56 pounds, every ounce of which was good; and they had pigs and poultry. The juice of the cocoa-nut and water appeared to be their only beverage. Their arms were clubs, darts, lances, and bows and arrows. Their canoes, clumsily sewed together, had outriggers, and were worked by paddles and by sails. The men wore a wrapper round the loins, and the women a sort of petticoat reaching to the knee.

The natives of Mallicolo are called by Captain Cook "an ape-like nation," the most ugly, ill-proportioned people he ever met with, and different from all others, diminutive in their persons, dark coloured, with black hair, short and curly, but not so woolly as a negro's; they had long heads, flat faces, and monkey countenances; and a belt round the waist, pulled tight across the belly, made them look not unlike overgrown pismires. The women were equally ugly; and the dress of both sexes was in other respects the same as that of Tanna, as were also the productions of the island. Their houses were low, and covered with palm thatch.—See Dalrymple, Burney, Cook, &c.

New Caledonia. VII. This large island, surrounded with coral islets and reefs, was wholly unknown till Captain Cook in 1774 fell in with the north-western extremity in steering south-west from Mallicolo, from which it is distant not more than about eighty leagues. He anchored within a small island called Balabea, and opposite to the district Balade. This great island extends between latitude 20. 5. and 22. 30., in the direction of N.W. and S.E., about 250 miles long by 60 broad. The land bears a great resemblance to that of New South Wales, and many of its natural productions appeared to be the same, but the natives were different.

Natives. The inhabitants are represented as a strong, robust, active, well-made people, courteous and friendly, and not in the least addicted to pilfering, in which respect they differ from every other tribe of Australasia. They are nearly of the same colour as the natives of Tanna, and appeared to be a mixed race between that people and those of the Friendly Isles, or of Tanna and New Zealand, their language being a mixture of them all. Of the same disposition as the natives of the Friendly Islands, they were found to excel them in affability and honesty; and the women, like those of Tanna, were chaster than the females of the more eastern islands. They wear a petticoat of the filaments of the plantain tree, "at least six or eight inches thick, but not one inch longer than necessary for the use designed." They paint and puncture their bodies, and wear ear-rings, and necklaces, and bracelets, of tortoise and other shells. Both men and women have good features and agreeable countenances; and some of the men measure in height six feet four inches. Their hair is frizzled out like a mop, and is very black, coarse, and strong, but different from that of a negro. The rough mop-heads make use of "scratchers," composed of a number of sticks of hard wood, about the thickness of knitting-needles, fastened together at one end like a sort of comb; the women have their hair cropped short. The men wear a wrapper round the loins, made of the bark of a tree. Their houses resemble bee-hives, with peaked roofs, entered by a hole just big enough to admit a man bent double. The sides are of spars and reeds, and both these and the roof well thatched with dry grass. They boil their roots and fish in earthen jars. They have nets made of plantain fibres, and the sails of their canoes are of the same material. These vessels consist of two trees fixed together by a platform. They have plantations of sugar-canes, plantains, bread-fruit, and cocoa-nut, but none of them very productive. The whole appearance of the country, indeed, is described as unable to support many inhabitants. The greater part of the visible surface consists of barren rocky mountains; and though the plains and valleys appeared to be fertile, Captain Cook was of opinion that "nature has been less bountiful to it than to any other tropical island we know in this sea."

D'Entrecasteaux passed the opposite extremity of New Caledonia in 1792, when on his search after the unfortunate La Pérouse, but was prevented by a barrier reef of coral from approaching the coast; and, in the following year, he visited Balade on the N.W. The account of the inhabitants, as given by Rossel and Labillardière, differs altogether from that of Cook. But their own account of their transactions there, the confidence with which they straggled over the country, and the readiness of the savages to serve them, by no means warrant the bad character they have thought fit to give them. Labillardière thinks the inhabitants, as well as the vegetable productions, resemble those of Van Diemen's Land. There was no want of different kinds of esculent plants, though a great scarcity prevailed from drought or other cause when they arrived. Australasia. The young shoots of the *Hibiscus tiliaceus*, the fruit of the *Cordia sebestina*, the *Dolichos tuberosus*, *Helianthus tuberosus*, *Arum esculentum*, and *Macrorrhizon*, *Hypoxis*, *Aleurites*, figs, oranges, plantains, sugar-canes, cocoa-nuts, and the bread-fruit, all afforded them articles of food. Yet Labillardière says they eat steatite, and that he saw one man devour a piece of this stone as large as his two fists. They also eat a species of spider. They had lost the hogs which Cook left them, but some half-dozen of cocks and hens were seen by the French.—See Cook, Labillardière, &c.

New Zealand. VIII. Though these islands geographically belong to Australasia, the natives are, in their physical character and language, Polynesians. They were first discovered on the 13th December 1642, by Abel Jansen Tasman, on his voyage of discovery from the Mauritius; and, on the 18th, the Heemskirk yacht and the fly-boat Zeehaan came to anchor in a bay to which they afterwards gave the name of Moordenaar's or Murderer's Bay, and to the island that of Staaten Land, in honour of the states-general, and in the possibility that it might join the Staaten Land to the east of the Tierra del Fuego. "It is a fine country," says Tasman, "and we hope it is part of the unknown S. continent." The expedition of Hendrik Brower to Chili the following year cut off the latter Staaten Land from any continental connection, and the name of the former was then changed to that of New Zealand.

On the 19th a boat with thirteen natives came within a stone's throw of the Heemskirk. The language in which they hailed was unlike that of the Solomon's Islands, of which Tasman had a vocabulary. Their vessel consisted of two narrow canoes, joined together by boards, on which the people sat; their paddles, about a fathom long, were pointed at the end; their clothing appeared of mats or cotton, but their breasts were naked. They were invited on board, but in vain. The ships, however, were moved nearer in-shore, upon which seven double vessels came off. A boat, despatched from one ship to the other, had previously been attacked. Three men belonging to the Zeehaan were killed, and one mortally wounded; one of the killed was dragged into the canoes. After this, despairing of getting water or provisions, they weighed and set sail, twenty-two of the native boats following them, eleven of which were full of people. The ships fired, and the canoes returned to the shore.

The next visitor, at the distant period of a hundred and twenty-seven years, was Captain Surville, who in 1769 put into a bay on the north-eastern extremity, and gave it the name of Lauriston Bay. In the same year Lieutenant (afterwards Captain) Cook of the Endeavour, made the land on the 6th of October, the enormous height of which became the subject of much conversation; and the general opinion was, that they had now discovered the *Terra Australis Incognita*. This voyage, however, and the circumnavigation of the islands of New Zealand, entirely subverted the theory of a great southern continent. In 1772 Captains Marion du Fresne and Crozet put into the Bay of Isles, where the former and some of the crew were murdered by the natives. In March 1773 Captain Cook in the Resolution, with Captain Furneaux in the Adventure, revisited New Zealand, where the latter had a whole boat's crew with a midshipman murdered by the inhabitants. In 1776 and 1777 a third visit was made to these islands by Captain Cook. In these several visits he was accompanied by men well versed in every branch of natural knowledge; and in the *Voyages* of Cook and Forster will be found every species of information that the ferocious disposition of the inhabitants made it practicable to collect.

Description. The two great islands of New Zealand extend between latitude 34° and 48° south, longitude 166° and 179° east; that to the northward, called Eaheinomawe, is about 400 geographical miles long by 90 in medial breadth. The name

Australasia.

of the southern island is Tavai Poenammoo, which is about 450 geographical miles long by 95 broad. The former has a rich and fertile soil, well clothed with trees, some of them more than 20 feet in girth, and 90 feet high, without a branch. Some of them resembled spruce, and were "large enough for the mainmast of a 50-gun ship." The highest hills were covered with forests, the valleys with grass and shrubbery, and the plains were well irrigated with rills of clear water. The southern island is very mountainous; one peak, resembling that of Teneriffe, was estimated by Forster, but without sufficient data, at 14,000 feet in height: it was covered with snow in the middle of January. Both as to appearance and temperature, they may be considered as the British Isles of Australasia. Fahrenheit's thermometer in February was never higher than 66°, and was not lower in June than 48°.

A great part of the western side of these islands had, however, a desolate and inhospitable appearance; exhibiting ranges of yellow sandstone, or white sandhills, with scarcely a blade of verdure. It is worthy of remark, that this extraordinary difference prevails between the two coasts of South Africa, the two coasts of New Holland, and the two coasts of Van Diemen's Land.

Natives

The natives are stout and well-limbed, muscular, vigorous, and active, excelling in manual dexterity; their countenances intelligent and expressive, of an olive complexion, but not darker than a Spaniard. In the appearance of the women there is not much feminine delicacy; but on Cook's first visit they found them more modest and decent in their behaviour than any of the islanders they had met with. They were covered from the shoulders to the ankles with a sort of netted cloth made of the split leaves of the flax plant (*Phormium tenax*), the ends hanging down like fringes.

The black hair of the men is bound in a knot on the top of the head, that of the women is cropped; both sexes anoint their hair with rancid oil, and smear their bodies with grease and red ochre. The faces of the old men are covered with large furrowed black marks, generally spiral lines, and have a horrible appearance. The women wear in their ears pieces of cloth, feathers, sticks, bones, &c., and bracelets and anklets of bone, teeth, shells, &c. Captain Cook did not observe any appearance of disease, or bodily complaint, or eruption on the skin, or marks of any; and the most severe wounds healed most rapidly. Very old men, without hair or teeth, showed no signs of decrepitude, and were full of cheerfulness and vivacity. They are mild, gentle, and affectionate towards each other, but ferocious and implacable towards their enemies; and it unfortunately happens, that the little societies into which they appear to be divided, are in an almost perpetual state of hostility, which makes it necessary for them to dwell in happahs or villages, fortified with embankments, ditches, and palisadoes. They give no quarter, and feast with apparent relish on the bodies of their enemies, which they cut up and broil in holes dug in the earth; they suck out the brains, and preserve the skulls as trophies. They made no hesitation in devouring human flesh in presence of the English officers, and their provision baskets had generally a head or a limb of a human subject.

The only quadrupeds on the islands are pigs, dogs, and rats, the former of which they eat; but their principal food consists of fish, potatoes, and the bruised roots of fern. They cultivate, however, and with great neatness, sweet potatoes, eddas, and gourds, all planted in regular rows; and Cook observed near the villages both privies and dunghills. Their houses have a ridge-pole to the roof, which, with the sides, are built of sticks and grass, and lined with bark; they sleep on the floors covered with straw; and the furniture consists of a chest to hold their tools, clothes, arms, and feathers, provision baskets, and gourds to hold water, which is their only beverage; the New Zealanders being among the very few people, civilized or savage, who are ignorant of the means of intoxication.

Their double canoes or whale-boats are admirably constructed with planks from 60 to 70 feet in length, and their prows and sterns are tastefully and curiously carved and ornamented; all of which is performed by adzes and axes of a hard black stone, or green talc or jade, and with chisels of human bone or jasper. Of these materials also their offensive weapons are made: these are lances fourteen feet long, sharp at both ends, of hard wood neatly carved; and a battle-axe of jade or bone about a foot long. Their war canoes carry from 60 to 70 men each; they keep exact time with their paddles, singing, with great vociferation and distorted features, their savage war-song, when bound on any hostile expedition. Their war-dances are conducted in the same furious and extravagant style: the only musical instrument, if it can be called one, which they use, is a triton shell, which sounds like a cow's horn.

Australasia.

They have, however, a taste for music, and the women are said to sing in a soft, slow, and mournful cadence, making use of semitones. When their husbands are slain in battle, they cut their legs, arms, and faces, with bone or sharp shells; and there are few of them who do not wear scars on their bodies as testimonials of their affection and sorrow for their deceased friends.

The natives of New Zealand exhibit a strange mixture of civilized and savage life. It was hoped, from the state of their cultivated grounds, of which several hundred acres were seen, that presents of hogs, kids, and poultry, would have been most acceptable, and considerable numbers were left with them on the first and second visits of Captain Cook; but, excepting the cocks and hens, which had bred plentifully, and flew about wild in the woods, the others had been wantonly destroyed. In 1791 Vancouver touched at Dusky Bay, and remained there for some time, examining the bays and creeks in the neighbourhood; but he did not see one human being. And in 1793 D'Entrecasteaux passed between the Three Kings' Island and Cape Maria van Diemen, but had no other communication with the natives except in their canoes. Unlike in some respects to the Tahitians, they have evidently a common origin; their language not differing more than the language of the two New Zealand Islands from each other. The few notions they have of superior beings also accord with those of Tahiti. (See Cook's *Voyages*.)

The following horrible transaction proves how well Captain Cook described the character of these cannibals. In December 1809, the ship Boyd, from Port Jackson, was at Wangaroa, in the Bay of Islands, and admitted, without due caution, too large a number of natives on board, when the crew were suddenly attacked, overpowered, and slaughtered. Captain Alexander Berry, of the ship Edinburgh Castle, being on the coast, was soon after apprised of this horrible event; and, proceeding to the bay, found the remains of the Boyd, which had been burnt by the savages. On landing, he discovered that the massacre had been directed by Tippahee, the old chief who had been so much caressed at Sydney. The bones of the unfortunate men lay scattered on the ground, where their bodies had been devoured by the savages. Sixteen were murdered and cut up on the deck of the vessel; five others, who had fled for safety upon the yards, were told by the old cannibal, that if they would come down their lives should be spared, which, after some hesitation, they consented to do. They were sent on shore, and in five minutes after their dead bodies lay on the beach. The only survivors which Captain Berry contrived to save, were a woman, two children, and a boy. Well might Captain Berry conclude the narrative of this horrid murder by an admonition, "Let no man trust a New Zealander."

The colonization of this group of islands by the British may well be considered an era in the history of Australasia. Little more than fifteen years has elapsed since the settlements of Auckland, Wellington, and other towns were established on the Waitemata, and the shores of Port Nicholson and other parts of the coast; and, though much bloodshed has followed the occupation of the lands of this warlike people—who are now known by their aboriginal name, Maori—the stranger may travel at the present day through their country, with as much security from robbery or violence as in civilized Britain. We speak from experience when we state that the stranger white man who goes amongst them with a peaceful object has everywhere the hand of fellowship held out to him, and is invited to partake of their hospitality. Strange to relate, but nevertheless true, the descendants of the old race of wild cannibals rarely speak of the practices of their fathers without horror, and exhibit the most pacific desire to trade with the Europeans, whom their progenitors never saw but to deceive and to devour. They have yielded to the all-powerful influence of Mammon; they love wealth; and they have become a subdued race by adopting the luxuries of the white man, which they cannot produce themselves. Where the missionaries failed in their attempts to bring them within the sphere of Christian civilization, and the strong arm of European warfare could not crush the indomitable spirit of these brave people, the slow but sure progress of commerce has laid that proud race submissively at the feet of the trading *Pakehas* (foreigners). The horrors of cannibalism are now becoming lost in the traditions of the past; for if the main cause of that practice was the desire for animal food, which could not otherwise be gratified in a region where no indigenous quadruped exists, the pigs, sheep, cattle, and vegetable produce of all kinds introduced by the settlers have now furnished them with abundance of the necessaries of life. A chief now, instead of leading his followers on to plunder and massacre the white men, may be seen walking into a banking office in Auckland or Wellington, and writing a cheque for a portion of his money deposited there; or sitting in a news-room perusing a newspaper

Australasia.

printed in his own language. The history of the British in New Zealand is replete with interest; but it does not admit of more than a brief notice in this place. For further details see NEW ZEALAND.

To the eastward of New Zealand is an island of considerable extent and well peopled, discovered by Mr Broughton in 1791, when on a voyage round the world with Vancouver. He called it Chatham Island. The people and the productions are the same as those of New Zealand. (See Vancouver's *Voyage*.)

Auckland Islands.

The Auckland Islands, or Lord Auckland's Group, are in Lat. 50. 40. S. and Long. 166. 35. E., nearly 180 miles S. of New Zealand. They were so named by the discoverer, Captain Abram Bristow, master of a South Sea whaler belonging to Mr Samuel Enderby, in gratitude to the nobleman whose name they bear, for having procured him admission, when a boy, into Greenwich Hospital. This group was first seen on the 10th of August 1806; and on the 20th of October 1807, Captain Bristow came to anchor with his ship the Sarah in a fine harbour in the largest island, which he quaintly named Sarah's Bosom. This harbour, sometimes called Laurie Harbour and Rendezvous Harbour, has been renamed Port Ross by Mr Chas. Enderby in honour of Sir James Clark Ross, who surveyed the port. These islands have subsequently been visited and briefly described by Captain Morell of the American merchant service in 1829; by Commodore Wilkes of the United States exploring expedition; and by Admiral D'Urville of the French, and Sir James Clark Ross of the English navy in 1840.

The group consists of one large and several smaller islands. The principal island, Auckland, is about 30 miles long and 15 broad, and contains about 100,000 acres of land. The smaller islands, of which the principal are Adam's and Enderby, contain together about 20,000 acres. They are all of volcanic formation, composed of basalt and greenstone, and present a wild and picturesque appearance. The highest hill (Mount Eden) rises about 1350 feet above the level of the sea. Crawley's Harbour in the south of Auckland is described by Captain Morell and others as even superior to Laurie's Harbour. This island is fertile and well watered. The hills, except a few of the highest, are thickly covered with lofty trees of most vigorous growth, while the plains and valleys are clothed with luxuriant vegetation. Dr Hooker, who, in his *Flora Antarctica*, has given an elaborate account of the botany of these islands, says, "The whole land seemed covered with vegetation. A low forest skirts all the shores, succeeded by a broad belt of brushwood, above which to the summit of the hills extend grassy slopes. On a closer inspection of the forest, it is found to be composed of a dense thicket of stag-headed trees, so gnarled and stunted by the violence of the gales, as to afford an excellent shelter for a luxuriant undergrowth of bright green feathery ferns, and several gay-flowered herbs. The climate is described by Captain Morell as "mild, temperate, and salubrious. I have been told," he adds, "by men of the first respectability and talent, who have visited the island in the month of July, the dead of winter on this island, that the weather was mild as respects cold, as the mercury was never lower than 38° in the valleys, and the trees at the same time retained their verdure as if it was midsummer. At the time we were there the mercury seldom rose higher than 78°, although it answered to our July. The weather is generally good at all seasons of the year, notwithstanding there are occasional high winds, attended with heavy rain."

The domestic pig, introduced by Captain Bristow, is the only quadruped found in these islands. The woods abound with singing birds, and on the shores seals and seafowl are plentiful. "The only game observed," says Dr Holmes of the United States expedition, "were a few gray ducks, snipes, cormorants, and the common shag. The land birds are excellent eating, especially the hawks." Some officers of the French expedition, who visited the E. coast between the two harbours, found the banks full of fish, with a regular bottom varying from 15 to 20 fathoms.

The convenience of these islands as a station for the southern whale fishery was remarked by the various navigators who visited them, but has only recently been taken advantage of. Mr Charles Enderby, F.R.S., and his two brothers, sons of Captain Bristow's employer, having obtained a grant of these islands from the British Government, a company was incorporated in 1849 for the prosecution of this important object.

Kerguelen's Land.

IX. Between the parallels of 40. 30. and 50. S., and longitude 69° E., lies the barren and uninhabited land of Kerguelen, so named from the French officer who first discovered it in 1772, and who, on a second visit in 1773, discovered some small islands near it, but on neither occasion was able once to bring his ships to an anchor upon any part of the coast. Captain Cook was more fortunate. He had heard of Kerguelen's discovery at the Cape of Good Hope, and wondered he should not have seen this land when he passed it so closely in 1770. In 1776, however, he fell in with these islands, and as no account of Kerguelen's voyage had been made public, he gave new names to each island. Speaking of the main island, "I should," says Cook, "from its sterility, with great propriety call it the *Island of Desolation*, but that I would not rob M. de Kerguelen of the honour of its bearing his name." He changed, however, the *Baie de l'Oiseau* of the French, where they had landed in a boat and lodged a piece of parchment in a bottle, into *Christmas Harbour;* and called a round high rock Bligh's Cap, which had been named by M. de Kerguelen the Isle of Rendezvous,—although, says Cook, "I know nothing that can rendezvous about it but fowls of the air; for it is certainly inaccessible to any other animal." Kerguelen thought he had discovered the *Terra Australis Incognita*, but Cook soon determined that it was of no great extent.

Australasia.

The hills were but of a moderate height, and yet in the middle of summer were covered with snow; not a shrub was found on this island, and not more than 17 or 18 different plants, one-half of which were either mosses or grasses. The chief verdure was occasioned by one plant not unlike a saxifrage, spreading in tufts, and forming a surface of a pretty extensive texture, over a kind of bog or rotten turf: the highest plant resembled a small cabbage when shot into seed, and was about two feet high. No land animals were met with, but great plenty of the ursine seal (*Phoca ursina*). Penguins were very abundant, as were also shags, cormorants, albatrosses, gulls, ducks, petterels, and sea-swallows. A few fish of the size of a haddock were taken with the line, and the only shell-fish were a few limpets and mussels.

The steep cliffs towards the sea are rent from the top downwards, but whether by rains, frost, or earthquakes, could not be determined. The productions of the hills were composed chiefly of a dark blue and pretty hard stone, intermixed with small particles of glimmer or quartz. Lumps of coloured sandstone, and of semi-transparent quartz, are also common. Nothing appeared like an ore or metal of any kind.—Cook's *Third Voyage*, vol. i.

St Paul and Amsterdam.

X. These small uninhabited islands are interesting only in a geological point of view. Situated in the midst of the great Indian Ocean, at the distance of 2000 miles from the nearest land, and removed but 18 or 20 miles from each other, they have no common point of resemblance; the one being the product of a volcanic eruption scarcely yet cooled, with a few mosses and grasses on its surface; the other composed of horizontal and parallel strata of rock, covered with frutescent plants—an appearance which led the scientific gentlemen in D'Entrecasteaux's expedition to conclude that an organization so regular could not proceed from a volcanic origin. A French seal-catcher from the neighbouring island had set fire to the shrubbery, which continued to burn when the navigators passed the island; and imagining that they saw smoke issuing from the crevices between the strata, some of them were disposed to consider this circumstance as infallible indications of subterranean fire. Perron, the seal-catcher above mentioned, with the gentlemen of Lord Macartney's embassy, who explored the southernmost island, Amsterdam, say that the shores of St Paul's abounded with pumice-stone.

Of the recent creation of Amsterdam there can be little doubt; indeed, it is scarcely yet cooled, and is altered considerably since its first discovery by Vlaming in 1696. From every part of the sloping sides of the crater, which is nearly 1000 yards in diameter, and into which the sea has forced its way, either smoke, or hot water, or hot mud, is seen to issue; and everywhere is felt a tremulous motion, and a noise heard like that of boiling water. In many parts of the crater, in the centre of which the water is 174 feet deep, the sea-water is tepid from the hot springs below; and numbers of these springs are found on the margin, below the high-water mark, of various temperatures, from 100° to the boiling-point. One very copious spring, slightly

Australasia.

chalybeate, flows in a copious stream into the crater, nearly on a level with the lowest state of the tide.

Another singularity which this island presents is in its mosses and grasses, which are all European. To these may be added the *Sonchus oleracea*, or sow thistle; the *Apium petrosilenum*, or parsley; and the *common Lycopodium*, or club-moss, which grows luxuriantly on the bleak heaths of North Britain, and seems to thrive equally well on the boggy soil of Amsterdam, heated, at the depth of a foot below the surface, to the temperature of 186° of Fahrenheit's scale.

The crater abounds with an excellent perch of a reddish colour, which is easily caught with the hook, and may then be dropped at once into one of the hot springs on the margin, and boiled. So caught and dressed, we are told it affords an excellent repast. The bar across the mouth of the crater is represented as one mass of cray-fish; and in the sea, outside the bar, the vast multitudes of whales, grampuses, porpoises, seals, and sea-lions, render it dangerous for boats to pass. It was the same in Vlaming's time, who "found the sea so full of seals and sea-lions that they were obliged to kill them to get a passage through. When they steered from the shore there was also an astonishing number of fish."

Coral reefs and islets in the Australasian Sea.

XI. From the volcanic island of Amsterdam, we must now take a glance of those innumerable low islands and reefs of rocks which are scattered over the greater part of the Australasian Sea to the eastward and northward of New Holland, and which are produced by an operation of nature different from that which lifted up Amsterdam; less violent, indeed, in its character, than that by which the latter emerged from the abyss, but affording a basis equally, if not more, solid and enduring. A volcanic island not unfrequently breaks down its supporters, and sinks back into the cavity out of which it was hurled, as was recently the case with the Sabrina Island, near St Michael's; but the island of coral, created by slow and imperceptible degrees, hardens with time, and becomes one solid mass from the summit to the base.

Throughout the whole range of the Polynesian and Australasian islands, there is scarcely a league of sea unoccupied by a coral reef or a coral island; the former springing up to the surface of the water perpendicularly from the fathomless bottom, "deeper than did ever plummet sound;" and the latter in various stages, from the low and naked rock with the water rippling over it, to an uninterrupted forest of tall trees. "I have seen," says Dalrymple, in his *Inquiry into the Formation of Islands*, "the coral banks in all their stages; some in deep water, others with a few rocks appearing above the surface: some just formed into islands, without the least appearance of vegetation; others with a few weeds on the highest part: and, lastly, such as are covered with large timber, with a bottomless sea at a pistol-shot distance." In fact, as soon as the edge of the reef is high enough to lay hold of the floating sea-wreck, or for a bird to perch upon, the island may be said to commence. The dung of birds, feathers, wreck of all kinds, cocoa-nuts floating with the young plant out of the shell, are the first rudiments of the new island. With islands thus formed, and others in the several stages of their progressive formation, Torres Strait is nearly choked up; and Captain Flinders mentions one island in it covered with the *Casuarina*, and a variety of other trees and shrubs, which give food to parakeets, pigeons, and other birds, to whose ancestors it is probable the island was originally indebted for this vegetation. The time will come—however indefinite that period may appear—when New Holland, and New Guinea, and all the little groups of islets and reefs to the N. and N.W. of them, will either be united into one great continent, or be separated only by deep channels, in which the strength and velocity of the tide may obstruct the silent and unobserved agency of these insignificant but most efficacious labourers.

Australasia.

A barrier reef of coral runs along the whole of the eastern coast of New Holland, "among which," says Captain Flinders, "we sought 14 days, and sailed more than 500 miles, before a passage could be found through them out to sea." Captain Flinders paid some attention to the structure of these reefs, on one of which he suffered shipwreck. "Having landed on one of these creations," he says, "we had wheat-sheaves, mushrooms, stags' horns, cabbage leaves, and a variety of other forms, glowing under water, with vivid tints of every shade betwixt green, purple, brown, and white." "It seems to me," he adds, "that when the animalcules which form the coral at the bottom of the ocean cease to live, their structures adhere to each other, by virtue either of the glutinous remains within, or of some property in salt water; and the interstices being gradually filled up with sand and broken pieces of coral washed by the sea, which also adhere, a mass of rock is at length formed. Future races of these animalcules erect their habitation upon the rising bank, and die in their turn, to increase, but principally to elevate, this monument of their wonderful labours." He says that they not only work perpendicularly, but that this barrier wall is the highest part, and generally exposed to the open sea, and that the infant colonies find shelter within it. A bank is thus gradually formed, which is not long in being visited by sea birds; saline plants take root upon it, and a soil begins to be formed; a cocoa-nut, or the drupe of a pandanus, is thrown on shore; land birds visit it, and deposit the seeds of shrubs and trees; every high tide and gale of wind adds something to the bank; the form of an island is gradually assumed; and last of all comes man to take possession. If we should imagine one of these immense coral reefs to be lifted up by a submarine volcano, it would be converted into an insular or continental ridge of hills of limestone.

It is worthy of remark, that, in this great division of the globe, fully equal in extent to that of Europe, there is no quadruped larger than the kangaroo; that there is none of a ferocious character, and, in many of the islands, none of any description. Man only in Australasia is an animal of prey; and, more ferocious than the lynx, the leopard, or the hyæna, he devours his own species, in countries too where nature has done everything for his comfort and subsistence.

The time is not far distant, however, when these inferior races must disappear before those exterminating influences to which we have already alluded, or their characteristic peculiarities be absorbed in the overwhelming tide of civilization. The same depopulating effects to which we have pointed in speaking of the aboriginal tribes in Australia and Tasmania, may be traced among the Maori race in New Zealand—a race which, fifteen years ago, was calculated at its lowest estimate to number 80,000 individuals. In vain do they strive to multiply their children, and to perpetuate their families by the most tender care. During our travels through the Kaipara country on the North Island, we observed chiefs with five, and as many as ten, wives, and only three or four sons and daughters; and we have heard Tirarau, chief of the Wairoa, lament in the following strain:—"I see the white man with one wife have ten children, while I with ten wives have only one child." It was melancholy to hear such remarks from these intelligent people, who are conscious of the decrease of their race; and that their lands will become peopled by the "Pakehas" when they are no more, as they are aware is the case throughout America. At a moderate calculation they are fewer by 12,000 now than they were fifteen years ago, when colonization was begun to any extent by Anglo-Saxon settlers, who have ever since kept up an indiscriminate intercourse with the Maori women. It is also observed, that the number of deaths is greatly above that of the births, which are chiefly a half-caste progeny. See NEW ZEALAND.

(J. B—W.) (S. M.)

AUSTRALIA,

Australia. Geography.

OR NEW HOLLAND, the largest island on the globe, is situated in the southern hemisphere; and, as described in the preceding article, forms the mainland around which are clustered those groups of islands which in modern geography constitute the *fifth* great division of the earth's surface. Wilson Promontory, its most southern angle, is in Lat. 39. 11. S., and Cape York, its northernmost headland, in Lat. 10. 43. S. Its greatest breadth from N. to S. is thus 1708 geographical miles, or 1965 statute miles. Cape Byron, the eastern limit, is in Long. 153. 37. E., and Cape Inscription, in 112. 55. E., forms its westernmost point; making the extreme length of the island from E. to W. about 2603 British miles, by an average breadth of 1200 miles—a tract of land well entitled to be called a continent, by which name it is frequently designated by geographers. Its superficies approximates to 2,690,810 square miles. That of the continent of Europe being 3,684,841 square miles, we can form some idea of its extent by comparison.

The nomenclature and geographical subdivisions of this island-continent have undergone many alterations from time to time, as the territory has become colonized. Before any settlement had been effected by the British Government upon its shores, the entire island was designated New Holland, not only by the Dutch—from whom it received its name—but on our own charts and maps. The E. coast, first discovered and explored by Captain Cook in 1770, was named by him New South Wales. The middle portion of the N. coast bore the name of Arnhem Land, after the ship of its discoverer Zeachen in 1618. The W. and S.W. coasts were named in like manner by their discoverers, the Dutch navigators, in the seventeenth century, De Witt's Land, Endraght's Land, Edel's Land, Leeuwin's Land, and Nuyt's Land. That of Van Diemen's Land was given by Tasman to what he supposed was the southern peninsula of New Holland, but which was afterwards discovered by Bass to be an island. The colonists have been anxious to name it after its discoverer, but the government still retain the first title.

Since this great territory has become the undisputed possession of Britain, other names, with the exception just mentioned, have, according to the law of nations, been substituted for the old Dutch titles. New South Wales is only applied now to about one-half the E. coast territory. The name of the entire island also is changed from New Holland to the more appropriate designation of Australia, by which it is now universally recognized and described. The subdivisions South, North, and Western Australia would be equally proper if their boundaries were defined according to the ordinary rules of geographical dissection. But while the first section, South Australia, is only the middle portion of the S. coast, trending inland to the central region; and the second, North Australia, embraces all to the N. of New South Wales; the third section, Western Australia, nearly bisects the island, leaving a small tract of land between it and South Australia with no name at all. A better division would be to draw a line right across from E. to W. in Lat. 26. S.; thus bisecting the island near its intertropical parallel; for although this line would be 3½ degrees S. of the Tropic of Capricorn, still the influence of the tropical rains and winds ascend even higher than this parallel. At all events this would be sufficient for us to designate the northern section *Tropical Australia*, and the southern *Temperate Australia*. Besides these two great meteorological divisions, they could conveniently be subdivided into four political sections by drawing another line from S. to N. in the meridian of 133. 30. Each of these sections might then be designated, according to its direction from the centre, South-western and North-western Australia, North-eastern and South-eastern Australia. And these again might be subdivided into provinces, as the last-named section includes the three colonies of New South Wales, Victoria, and South Australia. This arrangement would tend to simplify an important section of geography which at present is very much confused.

Australia. Geography.

If, for the better elucidation of our subject, we suppose these lines and boundaries to exist on the map, the northern or tropical division has little to do with the history of British colonization in Australia. It is within the temperate zone that our colonies have been planted and successfully nurtured. And this tract, again, separated by the meridian line suggested, confines to a still smaller compass the subject of our description. The group of colonies which absorb the attention of the statesman and merchant in that far-off land, are comprised within the last-named section, South-eastern Australia. On the W. it is bounded by a line drawn from the S. coast in Long. 132. E., meeting another line drawn at a right angle from the E. coast in Lat. 26° S.; the southern and eastern boundaries being formed by the coast line; which, by following the sinuosities of the gulfs and bays, comprehends a sea-board of nearly 2000 miles. Again, if a line be traced on the map, commencing about 150 miles inland from the head of Gulf St Vincent, and continued more or less (within half a degree) the same distance from the coast until it reaches the northern boundary line, the intermediate space will give a fair average of the extent of country at present colonized, which may be estimated in round numbers at 1500 miles long by 150 miles broad, or 225,000 square miles; or nearly three times the superficies of England.

This section of Australia is politically divided into three provinces; which, with the western colony and the unsuccessful settlements in the northern section, we shall treat of severally under the following heads:—

1. NEW SOUTH WALES.
2. VICTORIA, or PORT-PHILLIP
3. SOUTH AUSTRALIA.
4. WESTERN AUSTRALIA.

New South Wales.

I. NEW SOUTH WALES is bounded on the E. by the South Pacific Ocean; from Cape Howe to Wide Bay, forming a sea-board of 750 miles. A line drawn from Cape Howe in a N.W. direction inland, crossing the Australian Alps to the source of the Murray River, and continued along the N. bank of that stream, as far down as 141. E. Long. is the southern boundary. From this point a line traced upon the map due N. until it forms a right angle with the parallel of 26. S., the northern boundary, constitutes its limits westerly. The jurisdiction, however, of the executive government and legislature of the colony, extends beyond the northern boundary as far as Cape York and Port Essington.

General History.

In reviewing the history of New South Wales from its first settlement, there are three distinct eras in its political, social, and commercial progress, which mark its short but eventful annals to the present time. Firstly, its foundation and existence as a penal settlement; when it depended solely on support from the mother country. Secondly, the opening of the colony to independent and bounty emigrants; who rendered it a self-supporting colony; and, thirdly, the recent gold discovery, which has made it one of the most wealthy and self-dependent provinces of our colonial empire. Each of these distinct eras has been marked by a complete change in the previous condition of the body politic, according as its destinies were influenced by a penal, a pastoral, and a mining population.

First period.

During the first period referred to, the history of New

Australia. South Wales may be considered solely an account of British colonization in the Australasian seas.

New South Wales. It was after the separation of the United States from this country that it was first proposed to establish a colony for the reception of convicts from Great Britain on the eastern shore of Australia, or New Holland as it was then called; and in the year 1787 preparations were completed for carrying the design into effect. On the 13th of May 1787, a fleet consisting of eleven sail of ships, including a frigate and an armed tender, and having on board 565 male and 192 female convicts, with 200 troops, and several of their wives and children, set sail from Portsmouth; and after a voyage of eight months, arrived at their destination on the 18th, 19th, and

Phillip, 1788. 20th of January 1788. Captain Arthur Phillip of the royal navy was appointed the first governor of the colony. Botany Bay, where it was proposed to fix the settlement, was found ill adapted for that purpose. In seeking for a more eligible situation, Captain Phillip entered the inlet to which Cook had given the name of Port Jackson, which he found one of the most capacious and safe harbours in the world, navigable for vessels of any burden fifteen miles from its entrance, indented with numerous coves, sheltered from every wind, and possessing the finest anchorage. Within this harbour, on the shores of Sydney Cove, thinly wooded, and the haunt of the kangaroo, but now marked out as the capital of the future empire, the British ensign was hoisted on the 26th of January 1788. They immediately proceeded to clear the ground, to land the live stock and the stores, and to establish the colony, amounting to 1030 souls. In its early progress the settlers encountered numerous obstacles, which it required extraordinary courage, and perseverance, and untiring industry to overcome. These arose from various causes,—from the extremely sterile soil around Sydney Cove, from which no industry could extract a sufficient supply of grain for the wants of the people; from the profligate habits of the convicts, which occasioned continual disorders among themselves; from their outrages on the natives, and the retaliation which these produced. It was some years before an adequate supply of provisions for the maintenance of the colony could be derived from the ungrateful soil. The settlers consequently depended on foreign supplies, which did not arrive, and they experienced the severest privations. The loss of the store-ship the Guardian, under the command of Captain Riou, when proceeding to their relief with a large supply of provisions and stores, was a severe blow to the prosperity of the colony; and the general distress was greatly aggravated by the unseasonable arrival of a convict ship with 222 female convicts on board, thus increasing the number of consumers without any addition to the stock of provisions. The consequence was a severe scarcity, during which the weekly rations were, in April 1790, two and a half pounds of flour, two pounds of rice, and two pounds of pork; the governor sharing equally with others in the common calamity. Even this allowance, barely sufficient for the wants of nature, could not have been afforded if the governor had not sent off upwards of 200 convicts and troops to Norfolk Island, which is about 21 miles in circumference, with a fertile soil. Here the settlers, with even smaller allowance than at Sydney, would probably have perished, but for an unlooked-for supply from a flight of aquatic birds alighting on the island to lay their eggs. Owing to the length of their pinions, they take wing with difficulty; and they were so numerous that from 2000 to 3000 were taken every night, besides an incalculable quantity of eggs, which was a seasonable supply, and saved the lives of this detachment from the main body. Every effort was made to obtain supplies from China, India, and the Cape of Good Hope. There were not at one period four months' provisions in the store on the most reduced scale, and several persons had already perished. Shortly after, three other vessels arrived with convicts, a large number of whom perished of the scurvy during the voyage. For about three years the settlers were in danger of starvation, and it was not till June 1790 that relief was afforded, by the arrival of three transports from the Cape; and in the following year a ship of war arrived at Sydney, conveying ten vessels, with 1695 male and 68 female convicts, after losing 198 on the passage. The arrival of this fleet changed the aspect of affairs, and gave the necessary stimulus to the industry of this rising community. Amid the difficulties with which the colony had to struggle, its improvement was not altogether neglected. Cultivation was begun, farms were established at Rose Hill (Parramatta), at other places two towns were commenced, and a few convicts were emancipated, and obtained grants of land as settlers.

Australia. New South Wales.

Governor Phillip embarked for England in December 1792, when Lieutenant-governor Grose succeeded to the government. He was succeeded, on the 15th December 1794, by Captain Paterson of the New South Wales Corps; and, on the 7th August 1795, Governor Hunter, a captain in the royal navy, arrived, and immediately entered on his important office. From the year 1792 the improvement of the colony was decisive and rapid. It was in 1789 that the first harvest was reaped at Parramatta; and in 1793 the settlers were enabled to sell corn to the public stores, which was purchased at a given price. Trade began to make its appearance; passage-boats were established between the towns of Sydney and Parramatta, and the settlers visibly increased. The bulls and cows that had been originally brought to the new settlement had, by the carelessness of the keeper, been suffered to stray into the woods, and every subsequent search had proved ineffectual, when a fine and numerous herd of wild cattle was at length discovered in the interior of the country, evidently the progeny of the animals which had been so long lost to the settlers. At the close of the year 1795, the public and private stock of the colony consisted of 57 horses, 227 head of cattle, 1531 sheep, 1427 goats, 1869 hogs, besides a numerous breed of poultry. The total quantity of land in cultivation amounted to 5419 acres. At this period the storehouses were so completely exhausted, that, on the arrival of Governor Hunter, there were no salt provisions in store; and the settlement was, as before, reduced to rations. The colony was in danger of falling back; and it was only the speedy arrival of a store-ship at this critical and distressing moment that saved it from destruction in the seventh year of its establishment.[1] At the commencement of the year 1800, the inhabitants had increased to 6000. The stock consisted of 203 horses and mares, 1044 cattle, 1024 sheep, 2182 goats, and 4017 hogs. The quantity of land sown with wheat was 4665 acres, with Indian corn 2930 acres, and with barley 82 acres.

Hunter, 1795.

Governor Hunter quitted the colony in the year 1800, on the 27th September, and was succeeded by Captain Philip Gidley King, R.N., who had effected the settlement on Norfolk Island. His administration lasted six years, and was distinguished by what is termed the "Irish rebellion," which broke out about the year 1804. Several hundred convicts attached to the government establishment at Castlehill, about 20 miles from Sydney, struck work and demanded their liberty; having armed themselves with pikes, they prepared for resistance. They were, however, overthrown after a brief contest by the troops at Vinegar Hill, a few miles from Parramatta, on the Hawkesbury road; a few were shot by the troops; the leaders were apprehended; three of them were led to instant death; two others were executed the following day at Sydney, three others at Castlehill, and the remainder returned quietly to their labour. There is no other instance of any insurrection in the colony by the convict population.

King, 1800.

Australia. New South Wales.

A printing-press had been established in the colony about the year 1795, by Governor Hunter, and in March 1803 the *Sydney Gazette* was published by authority. In 1800 a copper coin was issued by the government. The colony was at this time governed by general orders issued by the government. Captain King does not seem to have been adequate to the magnitude of the trust committed to him. He quitted the colony in August 1806, and was succeeded by Captain William Bligh, R.N., who was even less qualified than his predecessor. He had given ominous proofs of his incapacity as commander of the Bounty, where by his tyrannical conduct he provoked the men to a mutiny; and his selection for the delicate task of rearing up this infant colony evinced a marked indifference to its welfare which merits decided condemnation. His administration produced exactly the consequences which might have been expected. So unwarrantable was his tyranny, and especially his persecution of one influential person, noted alike for his public spirit and for his private virtues, that the colonists, with all the honest indignation of freemen, declared against his authority; and being aided by the officers and men of the New South Wales Corps, they deposed him, and marching up to the government-house, they dragged him from his concealment behind a bed, and carefully protecting his person and property, sent him on board a sloop of war, in which he set sail for Europe, after he had been governor for 18 months. He was succeeded by General Macquarie on the 1st January 1810; the government having in the meantime, from 26th January 1808 to the 28th December 1809, been successively administered by Lieutenant-colonels Johnstone, Foveaux, and Colonel W. Patterson. During the government of General Macquarie, which lasted for 12 years, the settlement made great progress in wealth and improvement. The population was increased by the influx of numerous convicts, and some new settlers; though it was not till a later period that the full tide of emigration began to set in towards Australia. By aid from the British treasury, many public buildings were erected, roads were constructed, and the colonists, compelled by a season of drought in 1813, and animated by the spirit of discovery, made their way over the barrier of the Blue Mountains, hitherto deemed impassable. It was in search of new pasturage, and by following the course of the Grose river, that a pass was at last found, and a road commenced in the following year, over this mountain range, whose summits were considered by the aborigines to be inaccessible, and who often declared that there was no pass into the interior.[1] One great principle of Governor Macquarie's administration was to encourage and bring forward the convict population. It was his maxim to consider the European life of every convict as past and forgotten; their arrival on the shores of Australia as a new era in their existence, in which the errors of the past might be entirely redeemed. It was a most enlightened and benevolent policy; and if he erred in carrying it into effect with too little discretion, as was alleged, it was the error of a generous mind. Under his rule the convicts were patronized; some were chosen to be magistrates; he conferred on others colonial situations of trust, along with liberal grants of land. But his further endeavours to introduce into respectable society those who had been branded as felons, were opposed by the invincible antipathies of the European settlers, who, though they agreed in countenancing and rewarding good conduct in the convict population, could not be persuaded that any after purity of life could thoroughly efface their original disgrace. Such an intermixture of classes could only be effected by the debasement of European manners, and by lowering the moral tone of society in the colony.

Bligh, 1806.

Macquarie, 1810.

The departure of Governor Macquarie, on the 1st December 1821, marks the close of the first era in Australian history, embracing a period of 34 years. During that time the convict-pioneers had cleared the wilderness, tilled the ground, constructed bridges, roads, and other public works, unaided by free labour or private capital, at an average expense of L.300,000 per annum to the British treasury, and a total cost, up to this date, of nearly L.10,000,000 sterling. The armies of inexperienced immigrants who subsequently opened up the resources of the interior, thus found the most difficult preliminary task in colonization already accomplished to their hands. Until the year 1820 the British government assisted free settlers to emigrate, by paying their passages, and giving them grants of land, at peppercorn rents, upon their arrival; allowing them, also, convict servants under the assignment system, at the public expense, and frequently giving them a bonus of live stock to commence with. Very few, however, availed themselves of these inducements; for there was no spot on earth at this period the name of which sounded more abhorrent in the ears of the British public than that of *Botany Bay*. The white population, therefore, consisting at this date of 29,783 souls, were three-fourths of them either prisoners of the crown or emancipated convicts; while scarcely one-third were females. They were distributed in small detached settlements along the coast and within the county of Cumberland, mainly employed in constructing public works; while a few were engaged in tilling the ground, and tending the sheep, cattle, and horses, thinly spread over the 19 counties of the colony, as yet but imperfectly explored. The pastoral live stock at this period did not muster more than 250,000 sheep, 5000 head of horned cattle, and a few hundred horses. The capabilities of the colony, however, for the growth of fine-woolled sheep were by this time fully ascertained; and the four merino rams and twenty ewes, first imported in 1803, under the superintendence of Mr Macarthur, rapidly increased. Still the amount of wool exported—the only produce of the colony available in a foreign market—was but a trifling set-off against the enormous expenditure for the maintenance of the colony; an expenditure, however, which the subsequent unparalleled growth of the free colonies of Victoria and South Australia has amply justified.

Australia. New South Wales.

Let us now, before passing from our first period, give a cursory glance at the statistics of 1851, the close of the second. The 30,000 inhabitants had increased in 30 years to 359,158 in the parent colony and its two younger neighbours, of whom not 10,000 were convicts, and about five-sixths were females. In that year, just before the gold discovery, the extent of country occupied by the flocks and herds of the colonists covered more than four times the area of the original 19 counties of New South Wales; and they could muster, on good pasture land, not far short of 18,000,000 of sheep, 2,500,000 head of horned cattle, and 150,000 horses. The value of their exports of wool and tallow alone for the preceding year exceeded L.3,000,000 sterling; and the public purse of the colony was not only independent of bounty from the mother country, but the expenditure for military establishments and gaols was disbursed out of the colonial revenue—the first example of the kind in the history of our colonial empire.

Second period. Sir T. M. Brisbane, 1822.

Major-general Sir Thomas Brisbane, K.C.B., a man of acknowledged science and talent, succeeded General Macquarie; and with his arrival commenced that influx of free immigrants, which gives a distinctive character to his and the succeeding administrations. As New South Wales became more and more a community of free British subjects, the acts of the governors were of less importance in marking the progress of events, than the efforts of the colonists themselves. Heretofore the orders of the governor were supreme; and there was none to demur against their acceptance and enforcement as laws. But these mandates,

[1] See *History of Australasia*, by R. Montgomery Martin, F.S.S.

Australia. New South Wales.

although adapted to the constitution of the colony as a penal settlement, in fact a huge gaol or penitentiary, were opposed by the free and independent settlers, who found them oppressive, and questioned their legality. Consequently the absolute authority with which Sir Thomas Brisbane entered upon the duties of his administration, was modified in the second year after his arrival. In 1823, an act was passed authorizing the king to appoint a local council consisting of seven members to assist the governor in making laws for the colony, subject to His Majesty's approval. This concession, however, was not enough to meet the demands of the free colonists, and disagreements ensued, in consequence of which the governor returned to England before the expiry of his term of administration; delegating his power to Colonel Stewart, who acted as lieutenant-governor from the 1st December 1825 to the 18th December 1826. He was succeeded by Lieutenant-general Sir Ralph Darling, who, during his harsh administration of five years, made himself still more unpopular. The public press had by this time two representatives in the colony, and the acts of the governor were unsparingly criticized. General Darling was forced to yield to the superior strength of public opinion, and left the colony on the 21st October 1831. His irresponsible acts, however, probably accelerated the improvement of the internal government of the colony. In 1829 a legislative council was formed, which passed an act to establish trial by jury, and several other beneficial measures. The free immigrants about this period pressed rapidly forward into the interior, and settled down amidst their multiplying flocks. Towns began to spring up on a hundred spots in the interior, and steam-boats were first launched on the Australian waters. In the mother country the spirit of colonization was alive; and a new colony was projected on free principles to occupy the waste lands of Western Australia. The samples of fine wools which arrived in the London markets vied with the finest fleeces of Germany and Spain; and the mania for emigration began to spread among the upper classes.

Sir R Darling, 1826.

The eighth governor of New South Wales was Major-general Sir Richard Bourke; the most statesman-like, and withal the most liberal-minded ruler the colony has yet had. Steering a middle course between Darling's tyranny and Macquarie's amiable weakness, he organized anew the relations between the independent settlers and the convict population. With mild yet firm rule he brought together the contending interests of the free and the bond. And wherever he deemed it necessary, he unhesitatingly established the institutions of the mother country; endeavouring to make the gentlemen settlers and their families realize that, in staking their fortunes on the prospects of the colony, they had not forfeited the privileges and immunities of their native land. To the state of public morals he especially directed his attention, and caused acts to be passed to regulate and endow public schools and places of worship. The waste lands of the crown were no longer granted to absentee holders, or at peppercorn rentals, but put up to public auction and sold to the highest bidder; the proceeds being employed to assist the emigration of free labour. This fund increased from L.3617 in 1831 to L.132,396 in 1836. The revenue from the customs likewise increased rapidly, from the extending commerce of the city of Sydney; its harbour being pronounced by maritime authorities to be the finest commercial port in the world. The returns of the prosperous condition of the colony under the sway of its judicious governor, attracted an increasing number of emigrants from Britain; and the harbour of Port Jackson was thronged with richly laden vessels, freighted by respectable families of moderate means, in search of the "Golden Fleece" within the territory of the no-longer-dreaded shores of Botany Bay. Even foreigners who had formerly shunned these shores as if infected by plague, now landed their luxuries in safety, for which they obtained high prices; while the more fortunate colonists rolled along in their carriages through stone-built streets, lined with handsome warehouses and public edifices. In the country, gentlemen's seats sprang up on all sides; and good turnpike roads intersected the settled districts, which were thronged by vehicles of the agricultural population bringing their produce to market. In fine, before fifty years this antipodal offshoot of British civilization had taken deep root, and already began to extend its branches to an unforeseen growth. In the far interior the settlers found that the pastoral limits of the old colony were insufficient for maintaining their increasing flocks; and the neighbouring colonists in Van Diemen's Land found themselves in similar circumstances. Some adventurous settlers from that colony crossed Bass's Strait to the mainland, and settled on the shores of Port Phillip. The people and government of New South Wales were not long in following up the enterprize, and annexing the surrounding territory to their colony. The result has been the formation of the most flourishing province in Australia, the gold colony of Victoria. At the same time took place the establishment of South Australia, on the shores of Gulf St Vincent—a detailed account of which will be found under its proper head in this article. The importation of so much wealth to the southern shores benefited still more the parent colony on the east coast; and the colony of New South Wales, upon the retirement of Governor Bourke on the 5th December 1837, had arrived at a state of prosperity unexampled in the history of British colonization. To his representations and exertions was attributed, as his crowning effort in establishing free institutions among the colonists, the virtual abolition of transportation to New South Wales in 1839. At his departure, he was followed by the heart-felt acclamations of the colonists, who, in grateful acknowledgment for his services to their adopted country, have erected a statue to his memory at the western gate of the Sydney domain.

Australia. New South Wales.

Sir R. Bourke, 1831.

From the 5th December 1837 to the 23d February 1838, Lieutenant-colonel K. Snodgrass administered the affairs of the colony. He was succeeded by Sir George Gipps. This appointment was an unfortunate circumstance both for the new governor and the colony. His preconceived opinions of the high prerogatives belonging to the crown, in consequence of the settlement having been originally established without the aid of free capital or labour, rendered his administration, which lasted eight years and a half, a period of bitter political hostility between his government and the entire community, especially the higher class of free and independent colonists: and although no Australian governor's domestic life was of a more unsullied character than his, the acerbity of his temper banished from his presence many experienced men, whose private counsel would have been most beneficial to the newly-appointed governor. By this time the social and moral condition of the people had undergone a surprising degree of improvement from the influx of free immigrants; this was not merely amongst the upper circles in Sydney, and on the estates of landed and stock proprietors, but among the community at large. A moral tone prevailed in domestic society throughout the colony quite equal to that existing in the best localities of the mother country. Besides these beneficial effects from the infusion of fresh and uncontaminated blood into the body politic, many of the new settlers were related to families of rank, and with the advantage of wealthy connexions in Britain, had come to engage in colonial pursuits with large funds in hand. It was not uncommon to meet with gentlemen having L.20,000 in cash, ready to invest in land or to purchase stock; while private associations sent out managers with sums varying from L.50,000 to L.100,000 for the purpose of growing wool, and producing tallow for export as a means of profitable investment. Joint-stock companies, also, were formed in the great metropolis, who despatched their staffs of officers, with paid-up capitals rang-

Gipps, 1838.

Australia. New South Wales.

ing from L.250,000 to L.1,000,000 sterling, to facilitate the operations of banking, effecting insurances and mortgages, so as to obtain a high interest for their money. Wealth flowed likewise into the treasury from the land sales and customdues as it never had done before, until the governor found a large surplus in the public coffers. The imports of British merchandise, and the exports of colonial produce, averaged as many pounds per head of population as in the Canadian provinces it amounted to shillings. During the year 1846, when Governor Gipps left the colony, the former amounted to L.1,320,000, and the latter to L.1,481,000, amongst a population of 190,000 people. Thus the material prosperity of the colony had progressed, uninfluenced by the contentions of the higher powers; and notwithstanding the reckless speculations of the people, which brought about a general bankruptcy in 1841–3, it is but fair to state that the successful progress of the colony, throughout all its monetary difficulties, was maintained by the indomitable energy and high intelligence of the upper class of colonists—the merchants, squatters, landholders, and the representatives of the people in the legislative council. The independent members of the legislature expressed their judgment on the measures of the governor and executive, by passing a vote of censure on the government, and rejecting a bill brought forward by the colonial secretary for the maintenance of the border police. This proved a final blow to the administration of Sir George Gipps, and served to hasten his departure, which took place on the 11th July 1846.

Lieutenant-general Sir Maurice O'Connell, commander-in-chief of the forces throughout Australasia, acted as governor between 11th July and the 3d August 1846, when his successor arrived and assumed the administration of affairs. This was the tenth governor of New South Wales. Sir Charles Augustus Fitzroy, K.G.H., who holds the appointment at present, and who has lately been invested with the power and title of governor-general of the Australian colonies, which gives him certain jurisdiction over the lieutenant-governors of Victoria, South Australia, Van Diemen's Land, and Western Australia. Happily the instructions from the home government allow greater latitude to the colonists in the management of their own affairs than under Sir George Gipps. The government of Sir Charles Fitzroy has been in consequence infinitely more popular than that of his predecessor. Two significant facts have recently occurred, which tend to show the amicable relations between the government and the elected representatives of the council. One was the council's voting a considerable increase to the colonial secretary's salary,[1] and handing him over back pay, with the full concurrence of all the elected members. The other was his Excellency recommending to Her Majesty that their speaker should receive the honour of knighthood in virtue of his office. This title was recently conferred upon Sir Charles Nicholson; but, not to form a precedent in such cases, it was bestowed upon him in consideration of his private virtues and eminent abilities.

Fitzroy, 1846.

An important act came into operation during the first year of the present administration, under the sanction of an imperial ordinance, to the effect that the squatters, who were formerly considered yearly tenants at will, occupying crown lands, should henceforth obtain leases of their sheep and cattle "runs" for eight and fourteen years; with right of pre-emption, and compensation for improvements on the land. This was a great concession to the colony on the part of the then colonial minister, Earl Grey; and has proved a boon to the pastoral interests. If he had dealt equally justly with the agricultural population, and lowered the high minimum price of land from L.1 to 5s. per acre, submitting parcels for sale in small sections, as petitioned for by the colonists, he would have been bestowing a benefit on the community at large, and offering advantages to the introduction of a yeomanry-farmer class who have never emigrated much to Australia. But that high minimum price on crown lands is still in force; and as long as it is so, the mass of the people will be an erratic labouring class; whereas, with a cheap and easy tenure in the land, they will become a fixed population in spite of the attractions of the gold fields. What made his measures still more obnoxious to the colonists, that minister endeavoured to renew transportation to New South Wales after it had been virtually abolished by a predecessor in office ten years before; and despatched several ship-loads of convicts to Port Jackson and Port Phillip, where they were landed under the specious name of "Pentonville Exiles." The colonists were immediately up in arms. They assembled in public, they petitioned, and nearly opposed by force the landing of the convicts, until the local government had to warn the imperial legislature of the consequences. Ultimately, delegates from the inhabitants of the three colonies, who had united and formed themselves into an *Anti-Convict League*, were despatched for England to place before Her Majesty the disastrous effects of a renewal of transportation under any form to their shores. They showed with great truth that the evils resulting from the introduction of a felon class amongst a mixed population of emigrants, who were enjoying all the privileges and institutions of a free people, was fraught with the most demoralizing results, would utterly close their colonies to the importation of free labour, and thereby tend to ruin their prospects. We have already pointed out the fact, and commented favourably upon the policy of selecting *pioneers* for the purpose of encountering the first hardships of a new colony such as this, from among the malefactors of the parent country, both as a punishment and means of reformation for the criminal; but we do not advocate the *continuance* of this description of labour after the colony has an abundance of free labour for all its wants. Not only is it prejudicial to the moral and social condition of the colony, but transportation under such circumstances becomes a reward instead of a punishment. These crying evils becoming apparent from the revolt of some convicts on board the hulks at Chatham, who demanded to be transported, and above all, the gold discovery, not only induced the government to accede to the representations of the delegate from the *Anti-Convict League*, Mr. J. C. King of Victoria, but, what was of equal importance to the colonies generally, to rescind the order which made Van Diemen's Land a penal settlement. The growing wealth and prosperity of Port Phillip—which until 1851 was a dependency of New South Wales—likewise induced the Queen's government in 1850 to grant the petition of the colonists in that section of Australia to be separated from the parent colony, and declare it to be a distinct province of the British crown under the title and name of Her Majesty, Victoria; at the same time granting to the new colony a representative legislature, besides extending the constitution of New South Wales. These concessions on the part of the imperial government are hopefully regarded by the colonists as the precursors of a more liberal policy in future on the part of the colonial office.

Australia. New South Wales.

The political emancipation of the colonists in Victoria, and the extended privileges granted to the people of New South Wales, immediately preceded the astounding gold discoveries in 1851; and, as if still further to enable the political economist to draw his inferences from these events, it so happened that, in the month of March, two months before the gold discovery, the quinquennial census of the population was recorded. From it and the annual statistical re-

[1] This office is at present (1853) ably filled by Mr Edward Deas Thomson.

turns, may be exhibited a correct view of the social condition and material prosperity of the colony of New South Wales in this eventful year, when, two months after the gold discovery, Port Phillip was separated from it, marking at the same time the close of the second, or pastoral era, in the history of the country. Thirty years had elapsed since emigrants in any considerable number began to settle in this land of the felon; and they had since increased and multiplied so greatly, that the prisoner population was lost in the general multitude. These industrious immigrants had tilled and replenished the soil of their adopted country, until the solitary plains and forests swarmed with their flocks and herds; and fields of yellow corn sprung up in desert places.

The population on the 1st March 1851 (exclusive of Port Phillip) was 189,951, of which 108,691 were males and 81,260 females. The general statistics on the 31st December 1850 gave:—Live stock in the colony, 5,660,819 sheep, 952,852 horned cattle, 63,895 horses, and 23,890 pigs; 69,219 acres under cultivation, exclusive of vineyards, 995 acres producing 103,606 gallons of wine. Imports, L.1,333,413. Exports, L.1,357,784, including 14,270,622 lb. of wool, valued at L.788,051; and 128,090 cwt. of tallow, valued at L.167,858. Ordinary revenue, L.248,613. Coin in the colony L.690,852. Paper currency, L.266,602. Shipping inwards 421, of 126,185 tons. Shipping outwards 506, of 176,762 tons. Mills: steam, 64, water, 38, wind, 26, horse, 30. Six woollen-cloth establishments producing 200,000 yards, 5 distilleries, 20 breweries, 3 sugar-refining manufactories, 16 soap and candle, 15 tobacco and snuff, 4 hat, 4 rope, 36 tanneries, 5 salting and preserved-meat establishments, 93 tallow-melting do., 1 gas-work, 7 potteries, 1 glass-work, 1 smelting-work, 13 iron and brass foundries, and 5 ship-building yards.

Altogether the aspect of affairs, and the future prospects of New South Wales prior to the gold discovery were of the most encouraging description. And while her material prosperity was satisfactorily recovering from the depression consequent on the monetary confusion in 1841–3; her social condition had reached a climax of unexampled security and freedom from crime. These favourable symptoms of national progress likewise extended themselves to a greater degree amongst the lesser population of the newly-separated colony of Victoria at this time. Five years, we believe, had elapsed since a public execution had been witnessed either in Sydney or Melbourne; the greatest desperadoes in the country having emigrated to California. The newly-arrived stranger, on walking through these young cities, was struck with the peaceable demeanour of the inhabitants, and the respect they paid to the constituted authorities. But the gold discovery, like some sudden stage transformation, changed this state of general tranquillity into a chaos of public crime and domestic confusion, universal Mammon-worship and selfish aggrandisement, which at one blow, in the course of a few months, dislocated the structure of society, and the machinery of the government.

Third period. The Gold Discovery.

From a letter written by Mr Edward Hammond Hargraves to the colonial secretary, dated the 3d April 1851, we learn that on the 12th of February previous he had discovered the existence of gold among the alluvium of the surface rocks over a large area of crown lands within the settled districts of the colony; which subsequently turned out to be from 20 to 30 miles beyond the town of Bathurst, an inland town 125 miles from Sydney. He was led to prosecute a search for the precious metal in that locality, from the similarity of that mountainous section of New South Wales to the auriferous regions of California, where he had successfully worked as a gold-digger. Governor Fitzroy was doubtful of the discovery, from the circumstance of a similar statement having been made to him two years before, by a Mr Smith of Berrima, who allowed the matter to drop on the governor's refusing to pay him a large fixed sum for the discovery. At the same time, Sir Roderick Impey Murchison, president of the Royal Geographical Society, and other eminent geologists in the colony and in England, had predicted the discovery of gold in the Australian mountain ranges, from their presenting similar characters, both geographically and geologically, to the gold-bearing mountains in Russia. Partly from these representations, and partly from the general claims of the colony to have its mineral wealth scientifically investigated, the government had just recently appointed Mr Samuel Stutchbury as geological surveyor; and that gentleman at this period was prosecuting his *stereotyped* researches not very zealously in the mountain ranges at a short distance from Mr Hargraves. It is worthy of notice, that gold had been found in its native state from time to time some 20 years previous, by a Scotch shepherd, who was known to have sold a large quantity to the jewellers in Sydney; having kept the secret so long from a fear, as he stated, that if any one dogged him to the spot, they might murder him. Notwithstanding these and other evidences which need not be specified, no one had prosecuted the search systematically before Mr Hargraves, who demonstrated the fact publicly and without delay, To him, therefore, is due all the honour of the discovery.

After having intimated to the government that he was satisfied to leave to their liberal consideration any reward or remuneration they chose to offer him for his discovery, he posted off to Bathurst, and announced to the astounded inhabitants that they were living within a day's journey of the richest gold mines in the world. Followed by a number of the enterprising inhabitants, he led the way to Summer-hill Creek, and there, in a romantic vale, surrounded by hills, where this streamlet wound its course round a picturesque point of land, they dug the auriferous earth from the adjacent bank, washed it in the stream, and found that the soil was mixed with grains of gold. These gold-pioneers who thronged to the first "diggings," reminded of the resemblance between their country and the rich gold mines mentioned in Scripture, called this spot the Valley of Ophir.

This was in May 1851, and it became the signal for the colonists in other parts of the territory to be up and doing. "Ascertaining the nature and description of the rocks occurring in the vicinity of the gold deposits, they immediately set to work in their own localities to search for the hidden treasure, instead of flocking with the multitude to the Bathurst mountains, concluding wisely that these comprised only a small section of the great mountain chain where it existed. Like the industrious tenants of an Australian ant-hill suddenly roused, the whole community of bushmen became alive amongst the rocks and valleys of the colony. Stockwhips and shepherd's crooks were thrown aside for pick-axes and shovels, with which these adventurous men might be seen exploring the gold regions, and with what success is now well known to the world."[1] The Turon River, Muckerwa Creek, Louisa Creek, Meroo Creek, Frederick's Valley, Abercrombie River, and Araluen Vale, had their hidden treasures exhumed by the industrious diggers. And in three months after the workings at Bathurst had been set in operation, the newly-erected province of Victoria, within seven weeks from the time of her separation from New South Wales, disclosed her treasures at Ballarat; and before the close of the year, the Mount Alexander gold region gave forth that astounding yield of the precious metal, to which no record of ancient or modern times can furnish a parallel.

1 Mossman and Banister's *Australia Visited and Revisited*, p. 179.

Australia. New South Wales.

The result of the latter discovery not only arrested the departure of the Victoria colonists who were flocking to the Bathurst Mountains, but afterwards turned the tide of adventurers from the parent colony to the greater attractions of the Mount Alexander gold fields, which threatened at one time to decimate the populations of Sydney and the surrounding townships.

The gold was not merely found in the scales or grains which at first came from the stream-washings at Ophir, but it was now dug up in large masses, varying from several ounces to many pounds in weight, which were familiarly called "nuggets" by the diggers, after the Californian name given to these *pepitas* or nodules; and in one instance, at Louisa Creek, 106 lb. weight of pure gold was found by an aboriginal shepherd, imbedded in the quartz matrix, which formed one solid block of about 3 cwt. Neither was it found in the beginning at any great depth in the ground, but in many localities lay scattered among the surface soil, and hung to the roots of trees and shrubs. So easily and plentifully did it come to the hands of the gold-seekers, that it bore the aspect (and such was the belief of many of the less-informed diggers) of having only then sprung into existence from the earth, or having recently been scattered over the land by some mysterious agency; instead of carrying along with it the geological fact that its veins are coeval with the primary rocks. It was also discovered that the convicts had built a bridge across a small stream on the Bathurst road to Carcoar, above the gold formation, and that they had unconsciously paved the road with broken fragments of the gold-quartz veins. Even in the streets of Bathurst and Melbourne, small particles of the precious metal were picked up by children in its natural bed: and several farmers and gardeners found that they had been ploughing, digging, sowing, and planting their grain and trees in the auriferous soil. A knowledge of these facts industriously circulated by the colonial press, throughout a community possessed of all the modern facilities of information, and keenly alive to the speculations of money-making, could not but fairly upset the minds of the people. Consequently, a gold-mania seized every class of colonists, to the temporary suspension of all industrial pursuits.

Then followed a heterogeneous scramble for the coveted ore throughout the length and breadth of the land; which spread like wildfire to the neighbouring colonies of South Australia, Van Diemen's Land, and New Zealand, threatening to depopulate them of their male adult inhabitants. Masons and bricklayers left unfinished buildings in the towns; shopmen left their counters, clerks their desks, sailors their ships; and artizans of every description threw up their employments, leaving their masters, and their wives and families to take care of themselves. All other interests were absorbed in the search for gold; scarcely any other subject was talked of, or thought of; and the mass of the people ran off to the "diggings"—as this new occupation was termed. Nor did the mania confine itself to the labouring classes, for "these were soon followed by responsible tradesmen, farmers, captains of vessels, and not a few of the superior classes; some unable to withstand the mania and the force of the stream, or because they were really disposed to venture time and money on the chance; and others because they were, as employers of labour, left in the lurch and had no alternative. Cottages became deserted, houses to let, business was at a stand-still, and even schools were closed. In some of the suburbs not a man was left, and the women were known for self-protection to forget neighbours' jars, and to group together to keep house."[1] The ships in the harbour also were in a great measure deserted; and instances were known, where not only farmers and respectable agriculturists found that the only thing they could do, seeing that the people employed by them had deserted, was to leave their farms and join their men in the golden scramble; "but even masters of vessels, foreseeing the impossibility of maintaining any control over their men otherwise, agreed to make up parties among them, abandon their vessels, and proceed with their crews to the gold fields."[2] The towns and their environs being thus drained of their labouring populations, the prices of provisions rapidly rose. The common necessaries of life reached famine prices; which fell heavily upon those depending upon salaries. This, coupled with the high wages demanded by domestic servants, forced the upper classes of society to dispense with their services, and the ladies had to perform the household drudgery. Clerks and others under government, and in public and private offices, finding it impossible to make both ends meet, threw up their appointments and rushed to the diggings, and even the constabulary force were leaving the towns unprotected. During this state of affairs, the government were obliged to raise the salaries of their officers, in order to maintain a sufficient staff for the public service, and to preserve the public peace, which was becoming sadly disturbed. The banks and mercantile firms were obliged also to follow their example.

Australia. New South Wales.

Meanwhile, the governments of New South Wales and Victoria—the two gold colonies—looked with apprehension upon the probable result of this gold-revolution amongst a pastoral population widely scattered over the country; a portion of whom had but recently been reclaimed from the ranks of the felon. Therefore, how to regulate the prosecution of this new pursuit on crown lands became a matter of grave consideration. The crime and anarchy which had prevailed in California upon a similar discovery, brought the worst fears to their recollection. Precautionary measures were promptly taken, and all the available military force—which was but slender—was called into requisition, assisted by the mounted police to maintain order and authority at the localities where the diggers were working; for at some places communities had assembled, and erected tents, with the rapidity of a military encampment, in larger numbers than were to be found congregated within the ordinary townships scattered over the country. A proclamation was issued asserting the right of the Queen's government to all gold or precious metals found on crown lands; and that every person digging therein in search of it, or any individuals trading or otherwise profitably employed at the diggings, must take out a monthly license and pay the sum of 30s. This measure was at once acceptable to the people; and gold-commissioners were appointed to see that it was carried into effect. Notwithstanding the excitement which prevailed at the first blush of the discovery, and during the subsequent discoveries in other localities, which drew from time to time one-half of the adult male population to the gold fields, to the honour of the people of New South Wales be it said, that no greater amount of crime existed in that colony during the following eighteen months than the usual average. "Everywhere," as stated in the despatches of his excellency the governor-general, "the gold-diggers were loyal, orderly, and obedient to the laws," and they cheerfully paid the fee of one shilling per diem for license to dig. The same flattering testimony cannot be borne to Victoria, where a Californian state of anarchy at one time threatened the subversion of all law and order; the consideration of which will be reserved for our remarks on that colony. At the close of 1851, six months' experience had proved the most satisfactory results as to the extent and richness of the gold deposits. In New South Wales, upwards of 20,000 licenses were issued; and the export sheet from the port of Sydney

[1] Lieut.-governor Latrobe's Despatches.

Australia. showed that 142,975 ounces, valued at upwards of half a million sterling, had left the colony.

New South Wales. By this time also, hundreds, nay, thousands, had ascertained that they were morally and physically unfit for the hard labour and privations to be encountered in the search for gold. The consequences were, that not only did many clerks, shopmen, and artizans, come back to their former occupations in the towns, but much distress was felt by those who had abandoned lucrative employments, which were shut against them on their return; in many instances impaired in health from exposure to the rigorous climate of the gold regions, which, it will be understood, were first worked in the winter season in Australia. The beneficial effects which accrued from this reaction in favour of the industrial pursuits, was the supply of labour to be had, although at exorbitant wages, for securing the wool-crop of the season. Not only was this evil result anticipated among others at the beginning of the gold discovery, but at many sheep and cattle stations in the far interior, the herds and flocks were abandoned by their keepers, and at that period nothing short of utter ruin to the pastoral interests of the colony hovered over the sheep-farmers and graziers. In one instance, an enterprizing squatter drove 26,000 sheep into one flock, which he shepherded with four trusty shepherds on horseback. Here, as in other matters, the gentlemen settlers and capitalists in the colony proved themselves equal to the occasion; and much consideration is due to them for assisting to maintain the peace and prosperity of the community, by their untiring energy and support given to the government, under such an unlooked-for event. And where at first the squatters anticipated a ruinous reduction in the value of their stock, the demand for sheep and cattle to supply the diggers with food raised the prices 50 per cent., while the landholders found new purchasers of land among the judicious and fortunate gold-diggers. So at the close of the year 1851, the prospects of New South Wales, on all sides, were most cheering, where the reverse was expected. The population had increased to 197,168 persons. The value of the imports was L.1,563,931, and the exports L.1,796,912. Thus, the average of the former for every man, woman, and child in the colony, would be at the rate of L.8 per head, and of the latter about L.9. The ordinary revenue = L.277,728; and the crown revenue L.208,969; the coin in the colony L.560,766; and the paper currency L.418,541. The wool exported = 15,269,317 lb., valued at L.828,342; the tallow 86,460 cwt., value L.114,168; and the gold 144,120 oz. 17 dwt., value L.468,336. Shipping inwards 553 vessels, of 153,002 tons, having 7955 men on board; and the shipping outwards 563 vessels of 139,020 tons, having 7988 men.

From the circumstance of gold mines having been hitherto only worked by barbarous or despotic nations, who from ignorance or policy shrouded their operations in mystery, our information regarding the extent and character of gold-bearing rocks throughout the world was of a very meagre description. The "great fact," therefore, of gold regions being discovered, and worked within territories claimed by the Anglo-Saxon race in California and Australia, is not only an event of considerable interest in the history of the world, but has proved of the utmost benefit to science, in determining this important question in auriferous geology. Not only was the gold found in the ordinary quartz matrix, but the reports of the geological surveyors of New South Wales have shown that it is found in granite at Araluen Creek; schistose or slaty rocks at the Turon; and in Frederick's Valley specimens were found of a ferruginous rock, beautifully dotted with globules of gold. It would seem, therefore, that gold is the most universally distributed of metals among the unstratified rocks, although found in greatest abundance in the quartz veins which intersect these rocks. However, the great bulk of the gold found in Australia has not been extracted from its matrices, but dug out of the gold alluvium formed by the disintegration of these rocks. Hence the gold mines in this region have received the familiar name of "diggings," from the practical-minded Americans and Australians. What are termed the "gold diggings," then, are spots where the miners have to dig pits from 10 to 50 feet deep before they arrive at the substratum of auriferous soil in which the particles of gold are found loosely imbedded. This subsoil is generally a stiff blue clay mixed with sand and gravel, and the pure metal appears in scales about the size and shape of bran or shellings; and in rounded grains and lumps varying from the size of a pin's head to the form and dimensions of flints as they occur in chalk, a specimen of which, when gilded, gives exactly the appearance presented by these gold nodules, or, as they are now universally called, "nuggets." This alluvium is collected and mixed freely with water in a tub, which is termed "puddling." After having undergone two or three washings, the residue is thrown into a cradle or wooden trough, with "cleets" or ribs fastened across the bottom, and a sieve at the head, which prevents large stones or lumps of gold from passing through. The cradle is then rocked and tilted to and fro, while water is poured over the auriferous sand or gravel. When sufficiently washed, the residue at the bottom of the cradle is examined carefully, the large pieces, if any, picked out, and the scales of gold separated from any foreign substance by further washing in a tin dish, until it is perfectly clean; after which a magnet is passed through it to extract small particles of iron-sand, which are frequently mingled with it. Upon reaching the "washing-stuff," as the "diggers" term the gold alluvium, they sometimes see the nuggets dotting the earth, and collected into heaps or "pockets," which they extract easily with the point of a knife. This pleasing operation to the fortunate digger is called "nuggeting." Again, a similar process is followed at some localities where the grains of gold lie on the surface of the ground, technically termed "forsicking."

Australia. New South Wales.

History, 1852. The crisis of the gold discovery having mingled among the records of the past, the colony of New South Wales was fairly started, in 1852, on the third era of her eventful history, which may be literally termed the golden era. Fresh discoveries of deposits of the precious metal occurred throughout the length and breadth of the land; but they all proved inferior in richness and quality to the gold fields of Victoria. At the same time the average yield per digger equalled that of the younger colony, where the population on the gold fields was five times greater. It would appear, however, from the reports of the government geologists, that the gold drift of New South Wales was more superficial, and contained a smaller percentage of metal than that of Victoria. It was in vain that the press argued the point, so as to turn the main tide of emigration to their shores, for while 2000 a-week were arriving in Port Phillip, there were scarcely so many per month landing on the shores of Port Jackson. Not only was the number of immigrants small, but there was a re-emigration of about three-fourths of them with old colonists to Victoria. The stockholders suffered immensely during that year, from the scarcity of hands to tend their herds and flocks. A large portion of live stock was sent to the boiling-down establishments, which increased the export of tallow from 86,460 cwts. in 1851, to 118,182 cwts. in 1852. On the other hand, the export of wool decreased from 15,268,473 lbs. in the preceding year to 11,068,974 lbs. Although that year did not produce such brilliant results in her material progress as that of the sister colony, yet she enjoyed a condition of comparative domestic comfort and public tranquillity. One great moral evil, however, was alarmingly on the increase amongst the labouring population, viz., that of drunkenness. Thus, whilst the government were rejoicing at the increase of revenue derivable from the customs, the sober colonists had

Australia. New South Wales.

to deplore the excessive importation of intoxicating liquors which furnished it. It was proposed to check the growing evil, by passing some stringent law similar to the Maine Liquor Law in America, but there were constitutional obstacles which would render such a law abortive.

1853.

The progress of the colony during 1853 compared with its previous advancement was in every way encouraging, both as regards its political condition and material prosperity; and so far as these concerned their own particular sphere, the community could look with pride upon the aspect of the country in the sixty-fifth year of its colonization. But in this year it became apparent that such a degree of progress was no longer any criterion to the world at large of its claims to be the first colony in the Australasian group. The gigantic strides which its former dependency Victoria had made in population and wealth during the previous two years, had raised that young province in the estimation of the world to be the most important British colony in the southern hemisphere. In the mother country the *prestige* of the parent colony was gradually being eclipsed by its offshoot, not only in the minds of the emigrating and commercial public, but in that of the government. Meanwhile the industrial pursuits of the colony were pursued with vigour, and many public and private works of utility, which had been stopped for a season, were resumed with energy. Amongst the most important was the commencement of a line of railway from Sydney to Goulburn, 125 miles on the road to Melbourne. The Australian Steam Navigation Company likewise had their fleet of steam-vessels increased, so that the means of transit, internally and externally, were being made more effective in opening up the resources of the colony. In common with the neighbouring colonies, New South Wales benefited by the establishment of steam communication with the mother country. A line of steamers was laid on between Australia and Singapore, by the Peninsular and Oriental Company, conveying a mail every alternate month to join the overland mail from India to Europe, which carried news from the colonies to England in sixty-five days. Besides this route, there were occasional steamers made the voyage out *via* the Cape of Good Hope, and it was expected this could be accomplished in sixty days, but hitherto without success. In Sydney the formation of three new Anglo-Australian banks gave a speculative tendency to commercial transactions. The amount of bills under discount at the close of the year amounted to L.3,138,200; while the total assets of the banks were L.7,660,900, against L.6,550,800 of liabilities, leaving only L.1,110,100 as the working capital. When gold was low in price and sovereigns scarce, the colonists petitioned the home government to send them a mint to coin sovereigns in the colony. It arrived about this time, and there were more sovereigns in the colony than was required for circulation. Consequently the expensive machinery of which it consisted became of no avail. Moreover, it was found that coins from the colonial mint would not be current as a legal tender beyond the Australian possessions.

1854.
